Acknowledgments

This interdisciplinary work would not have seen fruition without the tireless, dedicated, and selfless support of one very important person, Robin Taylor. Robin is a driver of details. Her undaunted enthusiasm, drive for excellence and tirelessness inspires all of those who engage and know her. The links between editors, authors, administrators, and publishers have flown seamlessly under her watchful eye. As a managing editor, her skills remain without parallel.

Andrea Macaluso and all staff at Springer USA who are inspired leaders in publishing and medical biocommunication. Their leadership directed the need for such a comprehensive and interdisciplinary work but made themselves always available at even a moment's notice. We are proud to have linked with such talented individuals and ones so dedicated to the pursuit of excellence in all they do.

To our leaders and visionaries, John Gollan, Harold Maurer, Thomas Rosenquist, Clarence Ueda, and Carol Swarts, a simple thank you for all your support, through good times and bad, seems too simple. The gift of your ears and your thoughtful responses and unbridled determination to bring out only the best in us is appreciated beyond words.

To our chapter contributors and reviewers whose expertise and dedications were invaluable for completing the tasks at hand.

To Seiko Ikezu and Bonnie Bloch our partners in life journeys and best friends.

To Yohei and Michiko Ikezu and Soffia Gendelman, our parents, navigators, and visionary role models.

To Yumiko Aoyama for tireless support of family and research and Anthony Johnson for life lessons and mentorship.

To our children and sources of life joys, Clark and David Ikezu and Sierra and Adam Gendelman and Lesley Gendelman-Ehrenkranz and Miles Ehrenkranz.

We salute the *Journal of Neuroimmune Pharmacology* that provided the inspiration for this work. To Opendra (Bill) Narayan who passed away suddenly during the final completion of this work. Your mentorship, science, and personal contributions to us and to the field of neuroimmune pharmacology will be a lasting monument.

Tsuneya Ikezu
Howard E. Gendelman

Preface

In the past two decades, enormous strides have been made in our understanding of the relationships between inflammation, innate immune responses, adaptive immune responses, and degenerative human diseases. The developing information has mostly appeared in specialty journals that have dealt only with isolated aspects of these tightly related fields. As a result, contemporary scientists have had a difficult time finding sources, even in review articles, that provide an integrated picture. This volume, by assembling chapters that demonstrate the relationship between these historically separated fields, overcomes that difficulty. There are sections on immunology of the nervous system, diseases that result from immunological dysfunction, current therapeutic approaches, and prospects for the future. Overall, it integrates cutting-edge neuroscience, immunology, pharmacology, neurogenetics, neurogenesis, gene therapy, adjuvant therapy, proteomics, and magnetic resonance imaging. It is a rich harvest and readers will gain a perspective that has not previously been so readily available. Exposure to such a wealth of ideas is bound to inspire readers to undertake new and productive research initiatives.

The modern era of research into neuroinflammation and its relationship to neurodegenerative diseases began in the 1960's with the elaboration by Ralph van Furth of the monocyte phagocytic system. He injected labeled monocytes into animals and followed their migration and maturation into resident phagocytes in all body tissues. This provided closure between Metchnikoff's 1882 discovery of mesodermal attack cells in starfish larvae, which he named phagocytes, and del Rio Hortega's 1919 discovery of phagocytic mesodermal cells entering the brain, which he named microglia. Hortega's results had always been questioned and for more than two decades the controversy continued as to whether microglia were truly phagocytes of mesodermal origin or were merely typical brain cells of epidermal origin. Were they truly the effector cells in brain inflammation or were they merely housekeeping cells with an as yet undefined role? Resolving the controversy required development of the techniques of immunohistochemistry and monoclonal antibody production.

These tools for exploring brain biochemistry at the cellular level opened new vistas for understanding brain functioning and the pathogenesis of human disease. Using these tools, our laboratory and that of Joseph Rogers in Sun City demonstrated that HLA-DR was strongly expressed on activated microglia. The identification of HLA-DR, a well-known leukocyte marker displayed by antigen presenting cells, on these cells vindicated both Hortega and van Furth. The way was paved for many productive investigations exploring the properties of microglial cells and their relationship to inflammation and immune responses. This example of a conjunction between a fundamental concept and technical advances to establish its validity has been repeated many times since, as the chapters in this volume illustrate.

For a time, the concept that the brain is immunologically privileged held sway amongst neuroscientists. This was based on a narrow view that only the invasion of brain by lymphocytes could be taken as evidence of an inflammatory response. Since lymphocytes and antibodies are relatively restricted in their ability to cross the blood brain barrier, the brain was supposedly isolated from self-attack. But immunochemistry, coupled with newly developed molecular biological techniques, revealed that a spectrum of inflammatory mediators, including many known to cause tissue damage, were produced within the brain by resident brain cells. These discoveries required entirely new interpretations as to the nature of neuroinflammation and its relationship to immune responses. The innate immune system, operating at the local level in the brain, has clearly proved to be the first line of defense. Indeed, the basic discoveries from studying the response of brain in a variety of neurological diseases, is causing a reevaluation of a number of peripheral degenerative disorders where innate immune responses, which had previously been ignored, have been shown to play a critical role in their pathogenesis. In other words, those studying the brain are providing immunologists with revolutionary new concepts regarding classical peripheral diseases. The insights of Part 1 of this volume need to be interpreted in this broader context.

Part 2 moves from the general to the specific. Individual neurological disorders and details of their pathogenesis are presented. They involve disorders where innate immune responses predominate, as in Alzheimer's disease, to others such as multiple sclerosis, where adaptive immune responses predominate, and still others, which seem to involve both. We have suggested that diseases involving self-damage generated by innate immune responses be defined as autotoxic to differentiate them from classical autoimmune diseases where self damage is generated by adaptive immune responses. The common theme, however, is the involvement of microglia as the effector cells.

Part 2 also deals with neurogenetics. No field of neuroscience is moving so rapidly. The methodology for linking familial disease to DNA mutations commenced in the late 70's through identification of restriction fragment linked polymorphisms. By 1983, when James Gusella and his colleagues demonstrated a linkage of the G8 fragment to Huntington disease only about 18 markers were known. Now over 500,000 single nucleotide polymorphisms have been localized so that every centimorgan of the human genome can be explored. This advance has been coupled with rapid methods for sequencing DNA. The section on Genetics must be

regarded as the tiny tip of a giant iceberg where much below the surface will soon be revealed.

The ultimate objective of neuroscientists studying human disease is to find more effective treatments. Part 3 covers the pharmacology of existing drugs, as well as describing approaches now in clinical evaluation, and those still at the bench level. Some of these include concepts that depart from established therapeutic approaches giving the reader much food for thought.

To complete the picture, there is a final chapter on imaging of the brain. The brain is inaccessible, and imaging provides a view of how it functions in vivo and how it is affected by neurological disease. Most importantly, it now provides methods for objectively measuring the effects of therapeutic agents in diseases where progressive brain degeneration occurs.

In summary, this is a volume not to be put on the shelf as a reference text, but to be read cover to cover by aspiring neuroscientists.

Bethesda, MD, USA

William A. Banks, M.D.

Professor
Department of Internal Medicine
Veterans Affairs Medical Center-St. Louis
Saint Louis University School of Medicine
St. Louis, MO, USA

Elena V. Batrakova, Ph.D.

Research Assistant Professor
Department of Pharmaceutical Sciences
Center for Drug Delivery and Nanomedicine
College of Pharmacy
University of Nebraska Medical Center
Omaha, NE, USA

Richard A. Bessen, Ph.D.

Associate Professor
Department of Veterinary Molecular Biology
Montana State University
Bozeman, MT, USA

Keshore R. Bidasee, Ph.D.

Associate Professor
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Michael D. Boska, Ph.D.

Professor
Department of Radiology
University of Nebraska Medical Center
Omaha, NE, USA

William J. Bowers, Ph.D.

Associate Professor
Department of Neurology
Center for Aging and Developmental Biology
University of Rochester School of Medicine and Dentistry
Rochester, NY, USA

David B. Bylund, Ph.D.

Professor
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Carl B. Camras, M.D.

Professor and Chair
Department of Ophthalmology and Visual Sciences
University of Nebraska Medical Center
Omaha, NE, USA

Pawel S. Ciborowski, Ph.D.

Assistant Professor
Department Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Subhajit Dasgupta, Ph.D.

Research Associate
Department of Oral Biology
College of Dentistry
University of Nebraska Medical Center
Lincoln, NE, USA

Jean D. Deupree, Ph.D.

Professor
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Toby K. Eisenstein, Ph.D.

Professor and Co-Director
Center for Substance Abuse Research
Department of Microbiology and Immunology
Temple University School of Medicine
Philadelphia, PA, USA

Nathan Erdmann, B.S.

Graduate Student
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Howard J. Federoff, M.D., Ph.D.

Professor
Departments of Neurology and
Microbiology and Immunology
Center for Aging and Developmental Biology
University of Rochester School of Medicine and Dentistry
Rochester, NY, USA

Mary L. Filipi, M.S.N., Ph.D.

Assistant Professor
Department of Neurological Sciences
University of Nebraska Medical Center
Omaha, NE, USA

Kazunori Fugo, M.D. Ph.D.

Visiting Fellow
Viral Immunology Section
Neuroimmunology Branch
National Institute of Neurological Disorders and Strokes
National Institutes of Health
Bethesda, MD, USA

Howard E. Gendelman, M.D.

Professor and Chair
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Seymour Gendelman, M.D.

Clinical Professor
Department of Neurology
Mount Sinai Medical Center
New York, NY, USA

Anuja Ghorpade, Ph.D.

Professor
Vice Chair Cell Biology and Genetics
Director Brain Bank
University of North Texas Health Science Center
Fortworth, TX, USA

Ralf Gold, M.D.

Professor and Chair
Department of Neurology
St. Josef Hospital
Ruhr University
Bochum, Germany

Marcia N. Gordon, Ph.D.

Professor
Department of Molecular Pharmacology and Physiology
University of South Florida
Tampa, FL, USA

Paul H. Gordon, M.D.

Assistant Professor
Eleanor and Lou Gehrig MDA/ALS Research Center
Department of Neurology
Columbia University
New York, NY, USA

Christian W. Grant, Ph.D.

Fellow
Viral Immunology Section
Neuroimmunology Branch
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, MD, USA

G. Jean Harry, Ph.D.

Head, Neurotoxicology Group
Laboratory of Neurobiology
National Institute of Environmental Health Sciences
National Institutes of Health
Research Triangle Park, NC, USA

Kathleen M. Healey, M.S.N., Ph.D.

Nurse Practitioner
Department of Neurological Sciences
University of Nebraska Medical Center
Omaha, NE, USA

Terry D. Hexum, Ph.D.

Professor
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Yunlong Huang, Ph.D.

Post-Doctoral Research Associate
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Tsuneya Ikezu, M.D., Ph.D.

Associate Professor and Vice Chair for Research
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Steven Jacobson, Ph.D.

Chief
Viral Immunology Section,
Neuroimmunology Branch
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, MD, USA

Malabendu Jana, Ph.D.

Research Associate
Department of Oral Biology
College of Dentistry
University of Nebraska Medical Center
Lincoln, NE, USA

Michelle C. Janelsins, M.S.

Graduate Student
Department of Microbiology and Immunology
Center for Aging and Developmental Biology
University of Rochester School of Medicine and Dentistry
Rochester, NY, USA

Clinton Jones, Ph.D.

Professor
Department of Veterinary-Biomedical Sciences
University of Nebraska-Lincoln
Lincoln, NE, USA

Alexander V. Kabanov, Ph.D.

Professor
Department of Pharmaceutical Sciences
Center for Drug Delivery and Nanomedicine
University of Nebraska Medical Center
Omaha, NE, USA

David E. Kaminsky, B.S.

Center for Substance Abuse Research
Department of Microbiology and Immunology
Temple University School of Medicine
Philadelphia, PA, USA

Jonathan Kipnis, Ph.D.

Assistant Professor
Department of Neuroscience
University of Virginia
Charlottesville, VA, USA

Dennis L. Kolson, M.D., Ph.D.

Associate Professor
Department of Neurology
University of Pennsylvania School of Medicine
Philadelphia, PA, USA

Qingzhong Kong, Ph.D.

Assistant Professor
Department of Pathology
Case Western Reserve University
Cleveland, OH, USA

Leila Kump, M.D.

Chief Resident
Department of Ophthalmology
University of Nebraska Medical Center
Omaha, NE, USA

Helmar C. Lehmann, M.D.

Resident
Department of Neurology
Heinrich-Heine University
Duesseldorf, Germany

M. Patricia Leuschen, Ph.D.

Associate Professor
Departments of Genetics, Cell Biology
and Anatomy; Neurological Sciences
University of Nebraska Medical Center
Omaha, NE, USA

Miguel G. Madariaga, M.D.

Assistant Professor
Department of Internal Medicine
University of Nebraska Medical Center
Omaha, NE, USA

Eyal Margalit, M.D., Ph.D.

Associate Professor
Chief of Retina Service
Department of Ophthalmology
University of Nebraska Medical Center
Omaha, NE, USA

Clyde E. Markowitz, M.D.

Assistant Professor
Department of Neurology
Hospital of the University of Pennsylvania
Philadelphia, PA, USA

Eliezer Masliah, M.D.

Professor
Department of Neurosciences and Pathology
University of California San Diego
San Diego, CA, USA

Richard J. Miller, Ph.D.

Professor
Department of Molecular Pharmacology
and Biological Chemistry
Northwestern University School of Medicine
Chicago, IL, USA

Dave Morgan, Ph.D.

Professor
Department of Molecular Pharmacology and Physiology
Director of Basic Neuroscience Research
Director, Alzheimer Research Laboratory
University of South Florida
Tampa, FL, USA

R. Lee Mosley, Ph. D.

Assistant Professor
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Norbert Müller, M.D.

Professor
Hospital for Psychiatry and Psychotherapy
Ludwig-Maximilians-Universität
München, Germany

L. Charles Murrin, Ph.D.

Professor
Department of Pharmacology and Experimental Neuroscience
University of Nebraska Medical Center
Omaha, NE, USA

Prasad R. Padala, M.D.

Assistant Professor
Department of Psychiatry
University of Nebraska Medical Center
VA Medical Center
Omaha, NE, USA

Kalipada Pahan, Ph.D.

Abbreviations

Neuroimmune Pharmacology Abbreviations

¹ H	proton	AHSCT	autologous hematopoietic stem cell transplantation
¹ H-MRSI	proton magnetic resonance spectroscopic imaging	AICA	anterior inferior cerebellar artery
2D SDS-PAGE	two-dimensional polyacrylamide gel electrophoresis	AID	activation-induced (cytidine) deaminase
3'UTR	3'-untranslated region	AIDP	acute inflammatory demyelinating polyradiculoneuropathy
3HK	3-hydroxykynurenine	AIDS	acquired immunodeficiency syndrome
5-ASA	5-aminosalicylic acid	AIF	apoptosis inducing factor
5-HIAA	5-hydroxyindole acetic acid	AIRE	autoimmune regulator
5-HT	5-hydroxy tryptophan	AIS	anterior chamber associated immune deviation (ACAID)-inducing signal
5-HT	5-hydroxytryptamine	ALS	amyotrophic lateral sclerosis
6-OHDA	6-hydroxydopamine	AMAN	acute motor axonal neuropathy
8-OHdG	8-hydroxy-2'-deoxyguanosine	AMN	adrenomyeloneuropathy
γc	common γ-chain	AMPA	α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid
AAV	adeno-associated virus	AMSAN	acute motor-sensory axonal neuropathy
Ab	antibody	ANS	autonomic nervous system
Aβ	amyloid-β	AP-1	activating protein-1
ABP	actin-binding protein	APAF 1	apoptotic peptidase activating factor 1
AC	anterior chamber	APC	antigen presenting cells
ACAID	anterior chamber associated immune deviation	aPKC	atypical protein kinase C
αCamKII	α-calcium/calmodulin-dependent protein kinase II	aPL	antiphospholipid antibody
ACh	acetylcholine	APO1	apoptosis antigen 1 (Fas/CD95)
AChE	acetylcholinesterase	apoE	apolipoprotein E
ACTH	adrenocorticotrophic hormone (pro-opiomelanocortin; POMC)	APP	β-amyloid precursor protein
AD	Alzheimer's disease	APPs	acute phase proteins
ADAM	a disintegrin and metalloprotease	ARE	AU-rich response element
ADCC	antibody-dependent cellular cytotoxicity	ARMD	age-related macular degeneration
ADEM	acute disseminated encephalomyelitis	ART	antiretroviral therapy
AF	activation factor	ASL	arterial spin-labeled
Ag	antigens	ASTIN	acute stroke therapy by inhibition of neutrophils
AGE	advanced glycation endproducts	AT	adoptive transfer
AGM	aorta-gonad mesonephros	ATL	adult T cell leukemia
		AVP	arginine vasopressin
		AZT	3'-azidothymidine/zidovudine

BACE	beta-site amyloid precursor protein cleaving enzyme	CJD	Creutzfeldt-Jakob disease
BBB	blood-brain barrier	CLA	cutaneous leukocyte antigen
BCR	B-cell receptor	CLP	common lymphoid progenitor
BCRP	breast cancer resistance protein	CMAF	compound motor action potential
BDNF	brain-derived neurotrophic factor	CMC	critical micelle concentration
bFGF	basic fibroblast growth factor (FGF2)	CMP	common myeloid precursor
bHLH	basic helix-loop-helix	CMT	Charcot-Marie-Tooth (disease)
BHV-1	bovine herpesvirus-1	CMV	cytomegalovirus
BLIMP-1	B lymphocyte-induced maturation protein-1	CNG	cGMP-gated
BLV	bovine leukemia virus	CNPase	cyclic nucleotide 3' phosphohydrolase
BM	bone marrow	CNS	central nervous system
BMP	bone morphogenetic protein	CNTF	ciliary neurotrophic factor
BMVEC	brain microvascular endothelial cell	CO	cytochrome oxidase
BrdU	bromodeoxyuridine	COMT	catechol-O-methyltransferase
BRM's	biological response modifiers	Con A	concanavalin A
BSE	bovine spongiform encephalopathy	COP-1	copolymer-1
BTLA	B and T lymphocyte attenuator	COX	cyclooxygenase (prostaglandin-endoperoxide synthase; PTGS)
C/EBP	CCAAT box/ enhancer binding protein	CR	complement receptor
C3d	complement C3 fragment d	CRaBP	cellular retinal binding protein (retinaldehyde binding protein 1; RLBP1)
C4d	complement C4 fragment d	CRE	cAMP-responsive element
CA	cornu ammonis	Cre	creatine
CaMKII	calcium/calmodulin-dependent protein kinase II	CREB	cAMP-response element binding protein
CAMs	cell adhesion molecules	CRH	corticotrophin-releasing hormone
CARD15	NOD2/caspase recruitment domain 15	CRP	C-reactive protein
CB	cannabinoid	CRVO	central retinal vein occlusion
CB1	cannabinoid receptor 1	CSF	cerebrospinal fluid
CB2	cannabinoid receptor 2	CSF-1R	colony stimulating factor receptor
CBA	cytokine bead arrays	CSPG	chondroitin sulfate proteoglycans
CBF	cerebral blood flow	CT	computed tomography
CBF1	C promoter binding factor 1	CTA	computed tomographic angiography
CBP	cAMP-response element binding protein (CREB)-binding protein	cTEC	cortical thymic epithelial cell (TEC)
CBV	cerebral blood volume	CTL	cytotoxic T lymphocyte
CCT	central corneal thickness	CTLA-4	cytotoxic T lymphocyte antigen-4
CD	cluster of differentiation	CVO	circumventricular organ
CD11b	complement component 3 receptor 3 subunit (integrin alpha M; ITGAM)	Cx	connexin
CD40L	CD40 ligand (TNFSF5)	cyto c	cytochrome c
CDR	complementarity-determining region	D1R	type-1 family of dopamine receptors
CDV	canine distemper virus	D ⁹ -THC	D ⁹ -tetrahydrocannabinol
CFT	2-β-carbomethoxy-3β-(4-fluorophenyl) tropane	DA	Daniel's strain of Theiler's virus
cGMP	cyclic guanosine 5'-monophosphate	DA	dopamine
CGRP	calcitonin-gene related peptide	DAF	decay-accelerating factor
CHAT	choline acetyltransferase	DAG	diacylglycerol
CHN	congenital hypomyelinating neuropathy	DAT	dopamine transporter (solute carrier family 6A3; SLC6A3)
Cho	choline	DβH	dopamine-β-hydroxylase
CIDP	chronic inflammatory demyelinating polyradiculoneuropathy	DC	dendritic cells
CINC1	cytokine-induced neutrophil chemoattractant-1	DCX	doublecortin
		ddC	dideoxycytidine
		ddI	dideoxyinosine
		DG	dentate gyrus
		dGTP	deoxyguanosine triphosphate

DHA	docosahexaenoic acid	FDOPA	6-[(18)F]fluoro-L-dopa
Dhh	desert hedgehog	FFI	fatal familial insomnia
DIGE	Difference Gel Electrophoresis	FGF	fibroblast growth factor
DISC	death-inducing signaling complex	FID	free induction decay
DN	double/dominant negative	FIV	feline immunodeficiency virus
Doc2	double C2 protein	FKN	fractalkine (CX3CL1)
DOR	delta-opioid receptor	fMRI	functional magnetic resonance imaging
Dox	doxorubicin	Foxp3	forkhead box P3 transcription factor
Dox	doxycycline	FRC	fibroblastic reticular cell
DRPLA	dentatorubral-pallidoluysian atrophy	FRS2	fibroblast growth factor receptor substrate 2
DSI	depolarization induced suppression of inhibition	FS	Fisher syndrome
DSPN	distal sensory peripheral neuropathy	FTD	frontotemporal dementia
DSS	Dejerine-Sottas syndrome	FT-ICR	fourier transformed ion cyclotron resonance mass spectrometry
DTH	delayed-type hypersensitivity	Fz/PCP	Ffizzled/planar cell polarity
DTI	diffusion tensor imaging		
DWI	diffusion weighted imaging		
E2F	early-region-2 transcription factor	GA	glatiramer acetate
EAE	experimental allergic/autoimmune encephalomyelitis	GABA	gamma-aminobutyric acid
		GAD	glutamate decarboxylase
EAN	experimental allergic/autoimmune neuritis	GalC	galactocerebroside
		GALT	gut-associated lymphoid tissue
EAU	experimental autoimmune uveitis	GAP	GTPase activating protein
EBV	Epstein-Barr virus	GAPDH	glyceraldehyde 3 phosphate dehydrogenase
ECT	electroconvulsive therapy		
EDSS	expanded disability status scale	GBM	glioblastoma multiforme
EEG	electroencephalography	GBS	Guillain-Barré syndrome
EGC	embryonic germ cell	GC	germinal center
EGF	epidermal growth factor	GCDC	germinal center dendritic cell
EGFR	epidermal growth factor receptor	GCL	ganglion cell layer
ELAVL4	embryonic lethal, abnormal vision, Drosophila-like 4	GL	granular cell layer
		GC-MS	gas chromatography combined with mass spectrometry
eLTP	early long-term potentiation	G-CSF	granulocyte-colony stimulating factor
EMG	electromyography	Gd	gadolinium
EndoG	endonuclease G	GDF	growth and differentiation factor
EOAD	early-onset Alzheimer's disease	GDNF	glial-derived neurotrophic factor
EPI	echo-planar imaging	GEF	GDP-GTP exchange factor
EPSP	excitatory postsynaptic potential	GFAP	glial fibrillary acidic protein
ER	endoplasmic reticulum	GFP	green fluorescent protein
ERK2	extracellular signal-regulated kinase 2	GKAP	guanylate kinase-associated protein
ESC	embryonic stem cell	GLC1A	chromosome 1 open-angle glaucoma gene
ESI-MS/MS	electrospray ionization-mass spectrometry/mass spectrometry		
		Gln	glutamine
ET	endothelin	GM-CSF	granulocyte macrophage-colony stimulating factor
ETP	early T lineage progenitor		
		GMP	granulocyte monocyte precursor
FA	fractional anisotropy	GnRH	gonadotropin-releasing hormone
FAD	familial Alzheimer's disease	GPCR	G-protein-coupled receptor
fALS	familial amyotrophic lateral sclerosis	GPI	glycosylphosphatidylinositol
FasL	Fas ligand (FASLG)	GR	glucocorticoid receptor
FcγR-1	Fc receptor, IgG, high affinity-1	GRIP	glucocorticoid receptor-interacting protein
fCJD	familial Creutzfeldt-Jakob disease		
FcR	Fc receptor	GRO-α	growth-related oncogene alpha
FDC	follicular dendritic cell	GSH	glutathione
FDG	fluorodeoxyglucose		

GSS	Gerstmann-Straussler-Scheinker disease	IGF	insulin-like growth factor
GSTO1	glutathione s-transferase omega-1	IgG	immunoglobulin G
G ^T	G-protein transducin	IGIV	Immunoglobulin intravenous therapy
GUCY	guanylate cyclase	lhh	Indian hedgehog
HAD	HIV-associated dementia	IIDD	idiopathic inflammatory demyelinating disease
HAM/TSP	HTLV-I associated myelopathy/tropical spastic paraparesis	IκB	inhibitory kappa B
HAT	histone acetyltransferase	IKK	IκB kinase
HBsAg	hepatitis B surface antigen	IL	interleukin
HCMV	human cytomegalovirus	IL1RA	IL-1 receptor antagonist
HD	Huntington's disease	ILBD	incidental Lewy body disease
HDAC	histone deacetylase	ILM	inner limiting membrane
HES	hairly and enhancer of split homolog	IM	intramuscular
HEV	high endothelial venule	IMPDH	inosine monophosphate dehydrogenase
HFS	high frequency stimulation	iNKR	inhibitory natural killer cell receptor
Hh	hedgehog	INL	inner nuclear layer
HHH	hypervolemic-hemodilution and hypertensive	iNOS	inducible nitric oxide synthase (NOS2A)
HHV-6	human herpes virus-6	IOP	intraocular pressure
HIV-1	human immunodeficiency virus type 1	IP	interferon-inducible protein
HIVE	human immunodeficiency virus encephalitis	InsP3R	inositol 1,4,5-triphosphate receptor
HLA	human leukocyte antigen	IPL	inner plexiform layer
HLH	helix-loop-helix	IRAK	IL-1 receptor associated protein kinase
HMG-CoA	3-hydroxy-3-methylglutaryl coenzyme A	IRBP	interphotoreceptor retinoid-binding protein
HNE	4-Hydroxy-2-nonenal	IRF	interferon regulatory factor
hnRNP-A1	heterogeneous nuclear ribonuclear protein-A1	ISCOM	immunostimulating complexes
HPA	hypothalamic-pituitary-adrenal	ISH	in situ hybridization
HSC	hematopoietic stem cell	IT15	interesting transcript 15
Hsp	heat-shock protein	ITAM	immunoreceptor tyrosine-based activation motif
HSV	herpes simplex virus	ITGAM	integrin, alpha M
HSVE	herpes simplex virus-mediated encephalitis	ITR	inverted terminal repeat
HTLV	human T-cell lymphotropic virus type	IVDU	intravenous drug use
HTRA2	high temperature requirement serine protease 2	IVIg	intravenous immunoglobulin
Htt	huntingtin	JAK	Janus kinase
HvEa	herpesvirus entry mediator A	JEV	Japanese encephalitis virus
I-1	regulatory protein inhibitor-1	JNK	c-Jun N-terminal kinase
IBS	inflammatory bowel syndrome	KLH	keyhole limpet hemocyanin
ICAM	intracellular adhesion molecule	KOR	kappa opioid peptide receptor
ICAT	isotope coded affinity tags	KYN	kynurenine
ICH	intracerebral hemorrhage	KYNA	kynurenic acid
iCJD	iatrogenic Creutzfeldt-Jakob disease	LAK	lymphokine-activated killer (cell)
ICOS	inducible co-stimulatory molecule	L-AP4	L-2-amino-4-phosphonobutyric acid
Id	inhibitor of differentiation	LAT	latency associated transcript
IDE	insulin degrading enzyme	LB	Lewy bodies
IDO	indoleamine 2,3-dioxygenase	LC	locus coeruleus
IE	immediate early	LCA	leukocyte common antigen
IF	intermediate filament	LC-FTICR MS	liquid chromatography fourier transform
IFN	interferon	LC-MS	ion cyclotron resonance mass
Ig	immunoglobulin		liquid chromatography combined with mass spectrometry

LC-UV-SPE-NMR	liquid chromatography, UV detection, solid phase extraction, and nuclear	MHV	mouse hepatitis virus
LD	linkage disequilibrium	mI	myoinositol
LDL	low density lipoprotein	MIF	migration inhibitory factor
LFA-1	leukocyte function-associated antigen-1 (integrin beta 2; ITGB2)	Mint1	Munc-18 interacting protein 1
LGN	lateral geniculate nucleus	MIP	macrophage inflammatory protein
LIF	leukemia inhibitory factor	MJO	Machado-Joseph disease
Lingo-1	Leucine-rich-repeat and Ig domain containing Nogo-receptor interacting protein-1	MME	membrane metallo-endopeptidase (neprilysin)
LMN	lower motor neuron	MMP	matrix metalloproteinase
LOAD	late-onset Alzheimer's disease	MMSE	Mini-Mental State Examination
LOS	lipooligosaccharide	MNGC	multi-nucleated giant cell
LPA	lysophosphatidic acid	Mn-SOD	manganese superoxide dismutase
LPS	lipopolysaccharide	MOAT	multi-specific organic anion transporter
LRR	leucine-rich repeat	MOBP	myelin associated/oligodendrocyte basic protein
LRRK2	leucine-rich repeat kinase 2	MOG	myelin oligodendrocyte glycoprotein
LT	lymphotoxins	MOI	multiplicity of infection
LTD	long-term depression	MOR	mu opioid receptor
LTP	long-term potentiation	MOSP	myelin/oligodendrocyte specific protein
LTR	long-terminal repeat	MP	mononuclear phagocytes
LT-βR	lymphotoxin beta receptor	MPA	mycophenolic acid
MAC	membrane attack complex	MPL	monophosphoryl lipid A
MAdCAM-1	mucosal addressin cell adhesion molecule-1	MPO	myeloperoxidase
MAG	myelin associated glycoprotein	MPP ⁺	1-methyl-4-phenylperydinium
MAML	mammalian mastermind-like	MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MAO	monoamino-oxidase	MR	mineralocorticoid receptors
MAP	microtubule-associated protein	MRA	magnetic resonance angiography
MAPK	mitogen-activated protein kinases	MRI	magnetic resonance imaging
Mash1	mammalian achaete-scute homologue 1	MRP	multidrug resistance protein
MBGI	myelin-based growth inhibitor	MRS	magnetic resonance spectroscopy
MBP	myelin basic protein	MRSI	magnetic resonance spectroscopic imaging
MC-1R	melanocortin-1 receptor	MS	multiple sclerosis
MCMD	minor cognitive motor disorder	MSA	multisystem atrophy
MCP	membrane cofactor protein (CD46)	MSCs	myelinating Schwann cells
MCP-1	monocyte chemoattractant protein-1 (CCL2)	MSN	medium spiny neuron
M-CSF	macrophage-colony stimulating factor (CSF1)	mSOD1	mutant Cu ²⁺ /Zn ²⁺ superoxide dismutase 1
MD	major depression	MSRV	multiple sclerosis retrovirus
MDD	major depressive disorder	MT	magnetization transfer
MDM	monocyte-derived macrophages	mTEC	medullary thymic epithelial cell
MDP	muramyl-dipeptide	mTOR	mammalian target of rapamycin
MDP	monocytes and dendritic cell progenitor	MTR	magnetization transfer ratio
MDR	multidrug resistant	MUC1	mucin type 1 glycoprotein
MEG	magnetoencephalography	MuLV	murine leukemia virus
MEPP	miniature end-plate potential	Munc-18	mammalian homologue of unc-18
MFS	Miller Fisher syndrome	MVE	Murray Valley encephalitis virus
MHC	major histocompatibility complex	MZ	marginal zone
MHC-II	class II major histocompatibility complex	NAA	N-acetyl-aspartate
MHPG	methoxy-hydroxy-phenylethanolamine glycol	NAC	N-acetyl cysteine
		NADPH	nicotinamide adenine dinucleotide phosphate
		NCAM	neural cell adhesion molecule
		NE	norepinephrine

NET	norepinephrine transporter	OPCA	olivopontocerebellar atrophy
NeuN	neuronal nuclei	OPL	outer plexiform layer
NF	neurofilament	ORF	open reading frame
NF- κ B	nuclear factor- κ -B	ORN	olfactory response neuron
NFAT	nuclear factor of activated T lymphocytes	OSP	oligodendrocyte-specific protein
NFL	nerve fiber layer	OVA	ovalbumin
NFT	neurofibrillary tangles	P ₀	myelin protein zero
Ng-CAM	neuronal-glia cell adhesion molecule (L1/NILE)	p75 ^{NTR}	p75 neurotrophin receptor (nerve growth factor receptor; NGFR)
NGF	nerve growth factor	PACAP	pituitary adenylate cyclase activating polypeptide
NgR	Nogo-66 receptor	PAF	platelet activating factor
NICD	Notch intracellular domain	PAG	periaqueductal gray
NK	natural killer (cells)	PAMP	pathogen-associated molecular pattern
NKT	natural killer T (cells)	PARP	poly(ADP-ribose) polymerase
NMDA	N-methyl-D-aspartate	PASAT	Paced Auditory Serial Addition Test
NMDAR	N-methyl-D-aspartate receptors	PBBS	peripheral benzodiazepine binding sites
NMJ	neuromuscular junction	PBL	peripheral blood lymphocyte
NMO	neuromyelitis optica	PBMC	peripheral blood mononuclear cell
NMR	nuclear magnetic resonance	PBR	peripheral benzodiazepine receptor
NMSCs	nonmyelinating Schwann cells	PCP	phencyclidine
nNOS	neuronal nitric oxide synthase	PD	Parkinson's disease
NNRTIs	nonnucleoside analogue reverse transcriptase inhibitors	PD1	program death-1
NO	nitric oxide	PDGF	platelet-derived growth factor
NOS	nitric oxide synthase	PDTC	pyrrolidine dithiocarbamate
NOT	nucleus of the optic tract	PE	plasma exchange
NPC	neural progenitor cell	PEG	polyethylene glycol
NPY	neuropeptide Y	PEI	polyethyleneimine
NPZ-8	neuropsychological Z score for 8 tests	PENK	proenkephalin
NR	nuclear receptor	PERG	pattern electroretinogram
NRG	neuregulin	PET	positron emission tomography
NRL	nuclear receptor ligand	PG	prostaglandin
NRTI	nucleoside analogue reverse transcriptase inhibitors	Pgp	P-glycoprotein
NSAID	non-steroidal anti-inflammatory drug	PHF	paired helical filament
NSC	neural stem cell	PI	phosphatidylinositol
NSE	neuron specific enolase	PI3K	phosphatidylinositol-3-kinase
NSF	N-ethylmaleimide sensitive factor	PICA	posterior inferior cerebellar artery
NT	3-nitrotyrosine	PICK1	protein interacting with C kinase 1
NTF	neurotrophin	PKA	cAMP-dependent protein kinase
NVU	neurovascular unit	PKG	protein kinase G
OB	olfactory bulb	PLGA	poly(D,L-lactide-coglycolide)
OCB	oligoclonal band	PLP	proteolipid protein
OE	olfactory epithelium	PMCA	plasma membrane bound Ca ²⁺ -ATPase
OHT	ocular hypertension	PMD	Pelizaeus-Merzbacher disease
OL	oligodendrocyte	PMN	polymorphonuclear (leukocyte)
OLM	outer limiting membrane	PMP22	peripheral myelin protein 22
OMgp	oligodendrocyte-myelin glycoprotein	PNS	peripheral nervous system
OMP	olfactory marker protein	POAG	primary open-angle glaucoma
ONH	optic nerve head	polyQ	polyglutamine
ONL	outer nuclear layer	POMC	pro-opiomelanocortin
OP	oligodendrocyte progenitors	POU3F2	POU class 3 homeobox 2
OPC	oligodendrocyte progenitor cell	PP	protein phosphatase
		PPAR	peroxisome proliferator activated receptor

PPF	paired-pulse facilitation	SAPAP	SAP-associated protein (discs, large homolog-associated protein-1; DLGAP1)
PPG	poly(propylene glycol)	SAPK	stress-activated protein kinase (JNK, MAPK8)
PP-MS	primary progressive multiple sclerosis	sAPP	secreted β -amyloid precursor protein
PR	photoreceptor	SBMA	spinobulbar muscular atrophy
PrPc	cellular prion protein	SCs	Schwann cells
PrP ^{Pres}	protease resistance prion	SC	superior colliculus
PrPsc	disease-associated prion protein	SCA-3	spinocerebellar ataxia-3
PRR	pattern recognition receptor	scFv	single chain Fv antibodies
PS	presenilin (PSEN)	SCID	severe combined immunodeficiency
PSA-NCAM	poly-sialylated form of the neural cell adhesion molecule	sCJD	sporadic Creutzfeldt-Jakob disease
PSCs	perisynaptic Schwann cells	SCPs	Schwann cell precursor
PSD	postsynaptic density	sCrry	soluble complement receptor-related protein y
PSP	progressive supranuclear palsy	SDF-1	stromal cell-derived factor 1 (CXCL12)
PSW	periodic sharp wave	SEC	sinus endothelial cell
Ptc	patched, a hedgehog receptor	SELDI-TOF	surface enhanced laser desorption ionization time-of-flight
PTP	post-tetanic potentiation	SER	smooth endoplasmic reticulum
PVL	periventricular leukomalacia	SERCA	sarco(endo)plasmic reticulum Ca ²⁺ -ATPase
PVN	paraventricular nucleus	SERT	serotonin transporter
RA	rheumatoid arthritis	sFI	sporadic fatal insomnia
Rag	recombination-activating gene	SGLPG	sulfated glucuronyl lactosaminyll paragloboside
RAGE	receptor for advanced glycation end product	SGZ	subgranular zone
RANTES	regulated upon activation normal T-cell expressed and secreted (CCL5)	Shh	sonic hedgehog
RAS	renin-angiotensin system	sIg	surface immunoglobulin
Rb	retinoblastoma	sIL-2R	soluble IL-2 receptor
REM	rapid eye movement	SITA	Swedish interactive thresholding algorithm
RER	rough endoplasmic reticulum	SIV	simian immunodeficiency virus
RF	radiofrequency	SLE	systemic lupus erythematosus
RFLPs	restriction fragment length polymorphisms	SMAC	second mitochondrial-derived activator of caspase
RIM	Rab3-interacting molecule	SMase	sphingomyelinase
RIP	receptor interacting protein	SMN	survival motor neuron gene
RMS	rostral migratory stream	SN	substantia nigra
RNAi	RNA interference	SNAP	sensory nerve action potential
RNS	reactive nitrogen species	SNAP-25	synaptosome-associated protein of 25,000 daltons
ROCK	Rho kinase	SNARE	NSF attachment receptor
ROI	reactive oxygen intermediate	SNpc	substantia nigra pars compacta
ROR γ	retinoic-acid-receptor-related orphan receptor- γ	SNPs	single nucleotide polymorphisms
ROS	reactive oxygen species	SNS	sympathetic nervous system
RPE	retinal pigment epithelial (cells)	SOCS	suppressors of cytokine signaling
RR-MS	relapsing and remitting multiple sclerosis	SOD1	superoxide dismutase 1
RTK	receptor tyrosine kinase	SP1	specificity protein 1
rt-PA	recombinant tissue plasminogen activator	SPECT	single photon emission computed tomography
RT-PCR	reverse transcription polymerase chain reaction	SPG-II	spastic paraplegia type II
RyR	ryanodine receptor	SR-A	scavenger receptor type A
sALS	sporadic amyotrophic lateral sclerosis	SRBCs	sheep red blood cells
SAP	synapse-associated protein		

SREBP	sterol regulatory element binding protein	TOR1	target of rapamycin 1
SRF	serum-response factor	TRAF	TNF-receptor mediated factor
SSRI	selective serotonin reuptake inhibitors	TRAIL	TNF-related apoptosis inducing ligand (TNFSF10)
STAT	signal transducers and activators of transcription	TRANCE	TNF-related activation-induced cytokine (TNFSF11)
STP	short-term potentiation	TRANCER	TRANCE receptor (TNFRSF11A)
SV5	simian virus 5	TRE	tax responsive element
SVZ	subventricular zone	Treg	T regulatory cells
SWAP	short wavelength automated perimetry	Trk	receptor tyrosine kinase
T	tesla	TRP	transient receptor potential
TBE	tick-borne encephalitis virus	TSA	tissue-specific antigen
TBP	TATA-binding protein	Tyk2	protein tyrosine kinase 2
TCA	tricarboxylic acid	UACA	uveal autoantigen with coiled domains and ankyrin repeats
TCR	T-cell receptor	UMN	upper motor neuron
TCV	T cell vaccination	V1	primary visual cortex
TDO	tryptophan 2,3-dioxygenase	VAMP	vesicle-associated membrane protein
TE	echo time	VCAM	vascular cell adhesion molecule
TEC	thymic epithelial cell	VEGF	vascular endothelial growth factor
Teff	T effector cells	VEP	visual evoked potential
TF	transcription factor	VIP	vasoactive intestinal peptide
TG	trigeminal ganglia	VMAT-2	vesicular monoamine transporter-2 (solute carrier family 18; SLC18A2)
TGF	transforming growth factor	VZV	varicella-zoster virus
Th1	T helper type 1 cell	WKAH	Wistar-King-Aptekman-Hokudai
Th2	T helper type 2 cell	WNV	West Nile virus
TIA	transient ischemic attack	X-ALD	X-adrenoleukodystrophy
TIR	Toll/IL-1 receptor	XIAP	X-linked inhibitor of apoptosis protein
TJ	tight junction	ZO-1	zonula occludens-1 (TJP1)
TLR	toll-like receptor		
TMEV	Theiler's mouse encephalomyelitis virus		
TMT	trimethyltin		
TN	terminal nuclei		
TNF	tumor necrosis factor		
TNFR	tumor-necrosis factor receptor

Introducing Neuroimmune Pharmacology

Howard E. Gendelman and Tsuneya Ikezu

Keywords Neuroscience; Immunology; Pharmacology

Neuroscience, Immunology, and Pharmacology are broad disciplines that, without argument, impact upon a large component of what we come to know as biomedical science (Elenkov et al., 2000; Gendelman, 2002; McGeer and McGeer, 2004). Each, by themselves and even more so when put together, is multidisciplinary and require, for the student, both a broad knowledge and deep understanding of molecular and cellular biology. The linking of the disciplines is ever more challenging when they are placed together. The reasons are that each must first be understood as a single entity. The bridges between disciplines are what we now call multidisciplinary science and require another level of insight. When combined they form the basis of self, our engagement with the environment, as well as disease. Indeed, drugs that influence organ function, aging, and tissue homeostasis and repair can improve clinical outcomes.

A special feature of “human kind” among other species is the presence of an extraordinary complex immune system that can be used to protect against a plethora of harmful microbial pathogens, including viruses, bacteria, and parasites, as well as abnormal cells and proteins (Petranyi, 2002). This underlies the complexity of the human genome which encodes expansive immune-related genes not found in lower species (Hughes, 2002). When the immune system is compromised, disease occurs and often does with ferocity; a range of clinical manifestations ensue that follows as a consequence of neurodegenerative, psychiatric, cancer, and infectious diseases, or those elicited by the immune system’s attack on itself. The latter is commonly referred to as “destructive” autoimmunity (Christen and von Herrath, 2004). Interestingly enough, the immune system may sometimes be an impediment to therapy. Indeed, modulating its function is required for long term and successful organ transplantation (Samaniego et al., 2006). On balance, modulation of the immune system can affect “neuro-protective” responses for certain diseases (Schwartz, 2001).

Like the immune system, the nervous system contains surveillance functions and also possesses a number of functional roles that include mentation, movement, reasoning, sensation, vision, hearing, learning, breathing, and most behaviors. The

nervous system contains defined tissue structures such as the brain, spinal cord, and peripheral nerves. On the cellular level, it includes networks of nerve cells with a variety of functional activities, complex networks and communications, supportive and regulatory cells, called glia, and a protective barrier that precludes the entry of a variety of macromolecules, cells, and proteins. It also possesses connections throughout the body that permits it function. Neuroscience is the discipline used to explore each of the nervous system regions and cells that include their networks and modes of communication in health and disease. As humans we have 100 billion neurons that are each functional units contained within the nervous system. Molecular and biochemical studies along with cell and animal systems were each used alone and together to explore and define neural biology. The tasks of neurosciences are to better understand the brain’s function in the context of ontogeny, organism development, and aberrations during disease. Neuroscience is an interdisciplinary field and evolved as such during the past quarter of century. It includes neurobiology, neurochemistry, neurophysiology, mathematics, psychology, computer neuroscience, and learning and behavior. Even more recently, it has included the field of immunology (Sehgal and Berger, 2000). In a historical context, the brain, for a long time, was considered an immune privileged organ, meaning that its protective shield or barrier, commonly termed the blood–brain barrier, served to protect, defend, and as a consequence exclude ingress of toxins, cells, and pathogens (Streilein, 1993; Becher et al., 2000). Nonetheless, this is balanced by the fact that resident inflammatory cells do exist inside the brain and are capable of producing robust immune responses. In recent years, we have come to accept that it is the mononuclear phagocytes (MP; perivascular macrophage and microglia) that are disease perpetrators, while the astrocyte serves as “supportive” and “homeostatic” in nurturing neurons and in protection against the ravages of disease (Gendelman, 2002; Simard and Nedergaard, 2004; Trendelenburg and Dirnagl, 2005). The neuron in this neuroimmune model is the passive recipient of the battles that rage between the MP and the astrocyte. Findings that have emerged over the past half-decade have challenged this model. We now know that dependent upon environmental cues

and disease microglia, astrocytes, and other neural cell elements including endothelial cells and oligodendrocytes possess immunoregulatory functions. We also know that microglia and astrocytes dependent upon the environment and stimuli can be supportive, destructive or both. Even more importantly neurons can secrete immunoregulatory factors and engage directly into cell-cell-environmental cue stimulations. To make the system perhaps even more complex, local neuroimmune processes can result in the recruitment of T cells and enticement of the adaptive immune response, significantly affecting disease outcomes (Schwartz and Kipnis, 2004). All in all things appear more complex than once thought even in the past decade.

These three disciplines and the complexities inherent in each academic field is perhaps the most multidisciplinary serving to bring scientists and clinicians together with knowledge of neurobiology, immunology, pharmacology, biochemistry, cellular and molecular biology, virology, genetics, gene therapy, medicinal chemistry, nanomedicine, proteomics, pathology, and physiology. Even more than immunology and neuroscience, pharmacology integrates a broad knowledge in scientific disciplines enabling the pharmacologist a unique perspective to tackle drug-, hormone-, immune-, and chemical-related pathways as they affect human health and behavior. Drug actions and therapeutic developments form the basis of such discoveries but the central understanding of

how they act provide vision for further research to improve human well-being and health.

This textbook is unique in scope by serving to investigate the intersection of this new discipline. Neuropharmacologists study drug actions including neurochemical disorders underlying a broad range of diseases such as schizophrenia, depression, and neurodegenerative diseases (such as Alzheimer's and Parkinson's diseases). Drugs can also be used to examine neurophysiological or neurobiochemical changes as they affect brain, behavior, movement, and mental status. Immunopharmacology seeks to control the immune response in the treatment and prevention of disease. Research does include immunosuppressant agents used in organ transplant as well as developing agents that affect bone marrow function and cell differentiation in cancer therapies.

What then defines the field of *Neuroimmune Pharmacology*? Is it simply a field that intersects the three disciplines of neuroscience, immunology, and pharmacology in seeking to better define the epidemiology, prevention, and treatment of immune disorders of the nervous systems (Figure 1.1). Are these disorders limited in their scope in affecting behavior, cognition, motor and sensory symptoms, or do they also involve developmental and degenerative disorders? It is clear that the immune system is linked, in whole or part, to diseases that develop as a consequence of genetic abnormalities and a

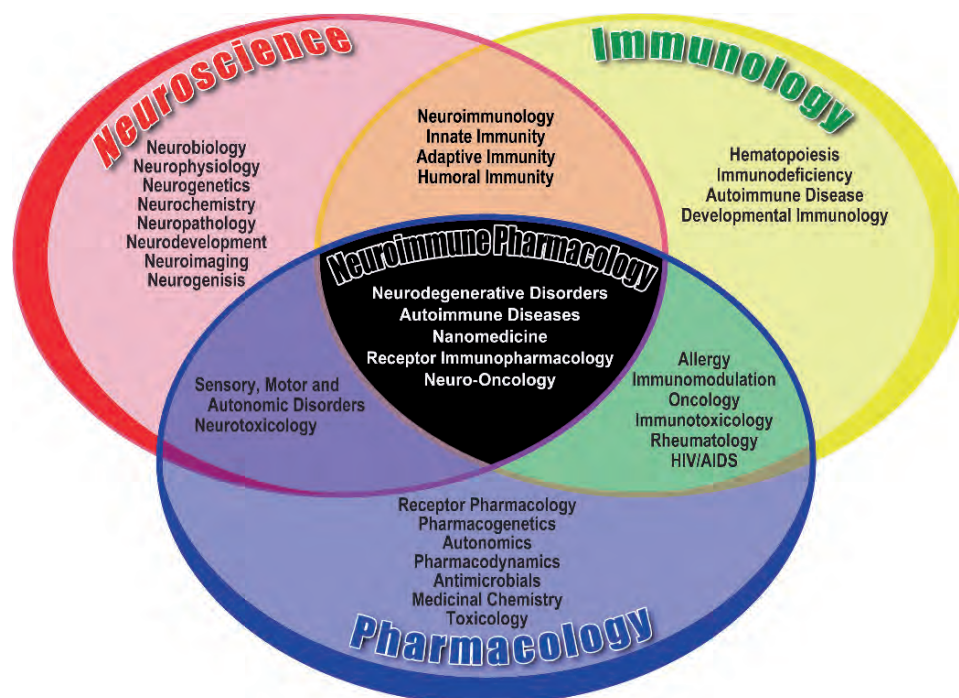

FIGURE 1.1. Neuroimmune Pharmacology. The intersection of the specific disciplines of neuroscience, immunology, and pharmacology are illustrated in this VENN diagram.

broad range of environmental cues (including microbial infections, and abused drugs), and toxins. So, where does Neuroimmune Pharmacology find its niche? These can occur, in part, as a consequence of neuropeptides, neurotransmitters, cytokines, chemokines, and abused drugs. Like much in science, we are left with more questions than answers. In the end, we seek avenues for translational research and better understanding of disease mechanisms. Diseases are together linked to microbial agents, by inflammatory processes, by emergence of cancerous cells or tumors, by stress, by environmental cues, and by genetic disturbances. No matter the cause harnessing the immune processes for pharmacological benefit will, at days end, provide “real” solutions to positively affect some of the most significant and feared disorders of our century.

What do we seek to accomplish by this textbook? First, we would be remiss in not acknowledging the pivotal discoveries made by others when research fields intersect (Rock and Peterson, 2006). These include the discovery and characterization of the guanosine triphosphate (GTP) binding and prion proteins (Gilman, 1995; Rodbell, 1995; Prusiner, 1998, 2001), neurotransmission and memory functions (Carlsson, 2001; Greengard, 2001; Kandel, 2001), and odorant receptors (Buck, 2000; Axel, 2005). We posit that new discoveries can and will be made through the intersections of Neuroscience, Immunology, and Pharmacology and as such sought to define it for the student. The notion that inflammation contributes in significant manner to neurodegeneration and significantly beyond autoimmune diseases is brought front and center and demonstrated without ambiguity for multiple sclerosis, peripheral neuropathies, Alzheimer’s and Parkinson’s disease, amyotrophic lateral sclerosis as well as for microglial infections of the nervous system including NeuroAIDS where microglial activation is central to disease processes (Appel et al., 1995; Toyka and Gold, 2003; McGeer and McGeer, 2004; Ercolini and Miller, 2005; Gendelman, 2002). Perhaps most importantly, we have laid the groundwork for how the immune system can be harnessed either through its modulation, through altering blood–brain barrier integrity and function, and/or by drug-delivery strategies that target the brain.

No doubt this textbooks is an expansive read for the student and scholar alike. To this end, we are humbled by its realization. These chapters lay only the beginnings to what we believe will be a large future footprint into the integration between neuroscience, immunology, and pharmacology.

Innate and Adaptive Immunity in Health and Disease

Howard E. Gendelman and Eliezer Masliah

Keywords Neuroinflammation; Innate and adaptive immunity; Neurodegeneration, Synapse loss

Neuroinflammatory processes play a significant role in health and disease of the nervous system. These regulate development, maintenance, and sustenance of brain cells and their connections. Linked to aging, epidemiologic, animal, human, and therapeutic studies all support the presence of a neuroinflammatory cascade in disease. This is highlighted by the neurotoxic potential of microglia. In steady state, microglia serve to protect the nervous system by acting as debris scavengers, killers of microbial pathogens, and regulators of innate and adaptive immune responses. In neurodegenerative diseases, activated microglia affect neuronal injury and death through production of glutamate, proinflammatory factors, reactive oxygen species, quinolinic acid amongst others and by mobilization of adaptive immune responses and cell chemotaxis leading to transendothelial migration of immunocytes across the blood–brain barrier and perpetuation of neural damage. As disease progresses, inflammatory secretions engage neighboring glial cells, including astrocytes and endothelial cells, resulting in a vicious cycle of autocrine and paracrine amplification of inflammation perpetuating tissue injury. Such pathogenic processes contribute to neurodegeneration. Research from others and our own laboratories seek to harness such inflammatory processes with the singular goal of developing therapeutic interventions that positively affect the tempo and progression of human disease (Crutcher et al., 2006).

As the life expectancy of the human population continues to increase, the possibility of developing neuro inflammatory and neurodegenerative diseases have increased considerably during the past 50 years. Of the neurodegenerative disorders, Alzheimer's disease continued to be the leading cause of dementia in the aging population. Traditionally, neurodegenerative disorders have been defined as conditions where there is selective loss of neurons within specific region of the brain accompanied by astrogliosis. However, in the past 20 years, we have learned that the pathological process leading to the disfunction of selected circuitries in the brain initiates with damage to the synapses rather than with the loss of neurons. In

fact, neuronal loss is a late event that is probably preceded by damage to axons and dendrites followed by shrinkage of the neuronal cell body and abnormal accumulation of filamentous proteins.

Therefore, the revised concept of neurodegeneration suggest that neuronal injury initiates at the synaptic junction and propagates throughout selected circuitries leading to neuronal dysfunction which resolves in the classical clinical symptoms characteristic to each of the neurodegenerative disorders (Hashimoto and Masliah, 2003). So, for example, in Alzheimer's disease early damage to the synapses between the entorhinal cortex and the molecular layer of the dentate gyrus (perforant pathway) resolves in the short-term memory deficits characteristic of this dementing disorder. Later on disconnection of the cortico-cortico fibers in the frontal, parietal, and temporal cortex resolved in more severe memory deficits, and alterations in executive functions, and abstraction. Degeneration of connections between the nucleus basalis of Meynert and the neocortex resolves in attention and memory deficits that usually associated with loss of cholinergic neurons. Other circuitries and neuronal populations are also affected in Alzheimer's disease illustrating the complexity of these disorders and the fact that the concept of single population is affected is limited. That is the case with several other disorders including Parkinson's disease where degeneration is not limited to the dopaminergic system, but also involves the limbic system, the raphe nucleus, the insula, and other systems.

In response to the injury neurons produce adhesions molecules and trophic factors that recruit astroglial and microglial cells to participate in the process of repair of the damage. In addition the microvasculature and other glial systems might also participate in the process. Thus, neurodegeneration is accompanied by astrogliosis, microgliosis, and microvascular remodeling. While astroglial cells initially produce trophic factors and cytokines that aid in the tissue repair, eventually these factors could amplify the inflammatory response, increase vascular permeability and result in microglial activation, which in turn might lead to the production of more proinflammatory cytokines and chemokines. A critical balance between

the repair and the proinflammatory factors often determines the future rate and progression of the degenerative process.

The understanding of the mechanisms of neurodegeneration and inflammatory response in these neurological conditions has seen a tremendous progress in the past 10 years. It is now recognized that probably small soluble misfolded protein aggregates denominated oligomers are responsible for the injury. So, for example, in Alzheimer's disease A beta protein oligomers might damage the synapses in the limbic system while in Parkinson's disease α -synuclein oligomers damage the axons in the striatum and cortical regions. While significant progress has been made in understanding the fundamental

mechanisms for the neuronal injury, less is known about the reasons for the selective neuronal vulnerability characteristic to these neurological conditions.

Anatomical Networks: Structure and Function of the Nervous System

Eliezer Masliah

Keywords Connectivity; Trafficking; Microcirculation; Synapses; Neuroanatomy; Cerebrum; Cerebellum; Brainstem

3.1. Introduction

The understanding of the gross and fine structure of the brain is of fundamental importance to elucidate how the nervous system works, how it interacts with other peripheral organs and tissues and how it responds to external stimuli. The functions and activity of the nervous system are not only regulated by its intrinsic wiring but also by interactions with cellular components of peripheral tissues. Of significant importance are the interactions between the nervous system with the immune and endocrine systems. While for the former, interactions involve trafficking of immune and hematopoietic cells into the brain; the latter interactions are primarily of a chemical nature, mediated by hormones and growth factors that reach the nervous system via the circulation.

In this context, the main objective of this chapter will be to provide an overview to the structure and organization of the nervous system that is relevant to the understanding of the unique interactions between the nervous and the immune system and to elucidate the pathogenesis of Alzheimer's disease (AD), Parkinson's disease (PD), HIV encephalitis (HIVE), and other neurodegenerative and neuroinflammatory disorders (Ringheim and Conant, 2004; Gendelman, 2002; Ho et al., 2005).

The central nervous system (CNS) has been traditionally considered an immunologically privileged site; however, it should be viewed as an immunological specialized region. In fact, cells from the immune system such as lymphocytes and macrophages constantly circulate through the nervous system under physiological conditions. Interactions between these trafficking immune cells and neuronal and glial components of the nervous system are critical in maintaining the stability and functional activity of selected neuronal circuitries involved in memory formation, sleep, and regulation of hormonal production (Avital et al., 2003; Opp and Toh, 2003). For example, a recent study

showed that trafficking of T-cells into the adult hippocampus contributes to maintenance of neurogenesis and learning (Ziv et al., 2006). Remarkably, recent evidence shows that not only does the immune system regulate neuronal function but also conversely neuronal activity regulates the immune response. For example, recent studies have shown that cholinergic neurotransmission is capable of inhibiting pro-inflammatory cytokine release and protects against systemic inflammation (Pavlov and Tracey, 2005).

Therefore, immunological reactions in the nervous system are not exclusively related to pathological conditions such as viral infections, autoimmune diseases, and inflammatory disorders (Owens et al., 2005; Eskandari et al., 2003) but also may be involved in regulation of neural homeostasis under physiological conditions and stress (Buller, 2003). In fact immune reactions that occur in the nervous system take a unique character which is probably determined by the very specialized local anatomy. Important anatomical characteristics of the nervous system that determine the unique nature of the neuro-immune reactions include the relative lack of lymphatic drainage, the lack of endogenous antigen presenting cells, and the selective permeability of the blood-brain barrier (BBB).

The distribution and patterns of migration of neuroimmune cells are regulated by genetically encoded programs, patterns of connectivity in anatomical regions and blood flow. Moreover, and as it will be described later, there are endogenously derived neuroimmune cells such as the astrocytes and microglia as well as cells derived from the peripheral circulation such as lymphocytes and macrophages. There are three routes for leukocyte entry into the nervous system: circulation through the subarachnoid space which is mediated by P-selectin, migration across the choroid plexus which is mediated by PECAM, and extravasation from postcapillary venules mediated by P-selectin, lymphocyte adhesion molecule (LFA-1) and intercellular adhesion molecule (ICAM) (Engelhardt and Ransohoff, 2005).

In summary, the nervous system has a unique circulatory organization based on the flow of the cerebrospinal fluid

(CSF), the microvasculature, the BBB and the regulation of the blood flow by the neural activity that provides a series of mechanisms to selectively regulate interactions between the nervous system and trafficking cells from peripheral tissues. This chapter provides the structural framework for the better understanding of these interactions under physiological conditions and in neurological diseases.

3.2. Gross Anatomical Structure of the Brain

3.2.1. General Organization of the Central Nervous System

3.2.1.1. Introduction

The nervous system is divided into the CNS and the peripheral nervous system (PNS). The CNS is composed of the brain and spinal cord and a triple membranous covering denominated meninges. The outer membrane is the dura, the intermediate

arachnoid, and the innermost pial membrane. The complexity of the CNS, with its millions of neurons and connections can be summarized to six major divisions: (1) cerebral hemispheres, (2) diencephalon, (3) midbrain, (4) pons and cerebellum, (5) medulla, and (6) spinal cord (Martin, 1989) (Figure 3.1). The PNS consists of nerves connected to the brain and spinal cord (cranial and spinal nerves) and their branches within the body (Crossman and Neary, 2005). Spinal nerves serving the upper or lower limbs join to form the brachial or lumbar plexus, respectively, within which fibers are distributed into named peripheral nerves. The PNS also includes some groups of peripherally located nerve cell bodies that are located within ganglia (e.g. dorsal root ganglia). Neurons that detect changes in, and control the activity of, the internal organs are denominated autonomic nervous system (ANS). Its components are present in both the central and peripheral nervous systems. The ANS is divided into two anatomically and functionally distinct components called the sympathetic and parasympathetic divisions, which generally have antagonistic effects on the structure that they innervate. The ANS innervates smooth muscle, myocardium and secretory glands and it is an important

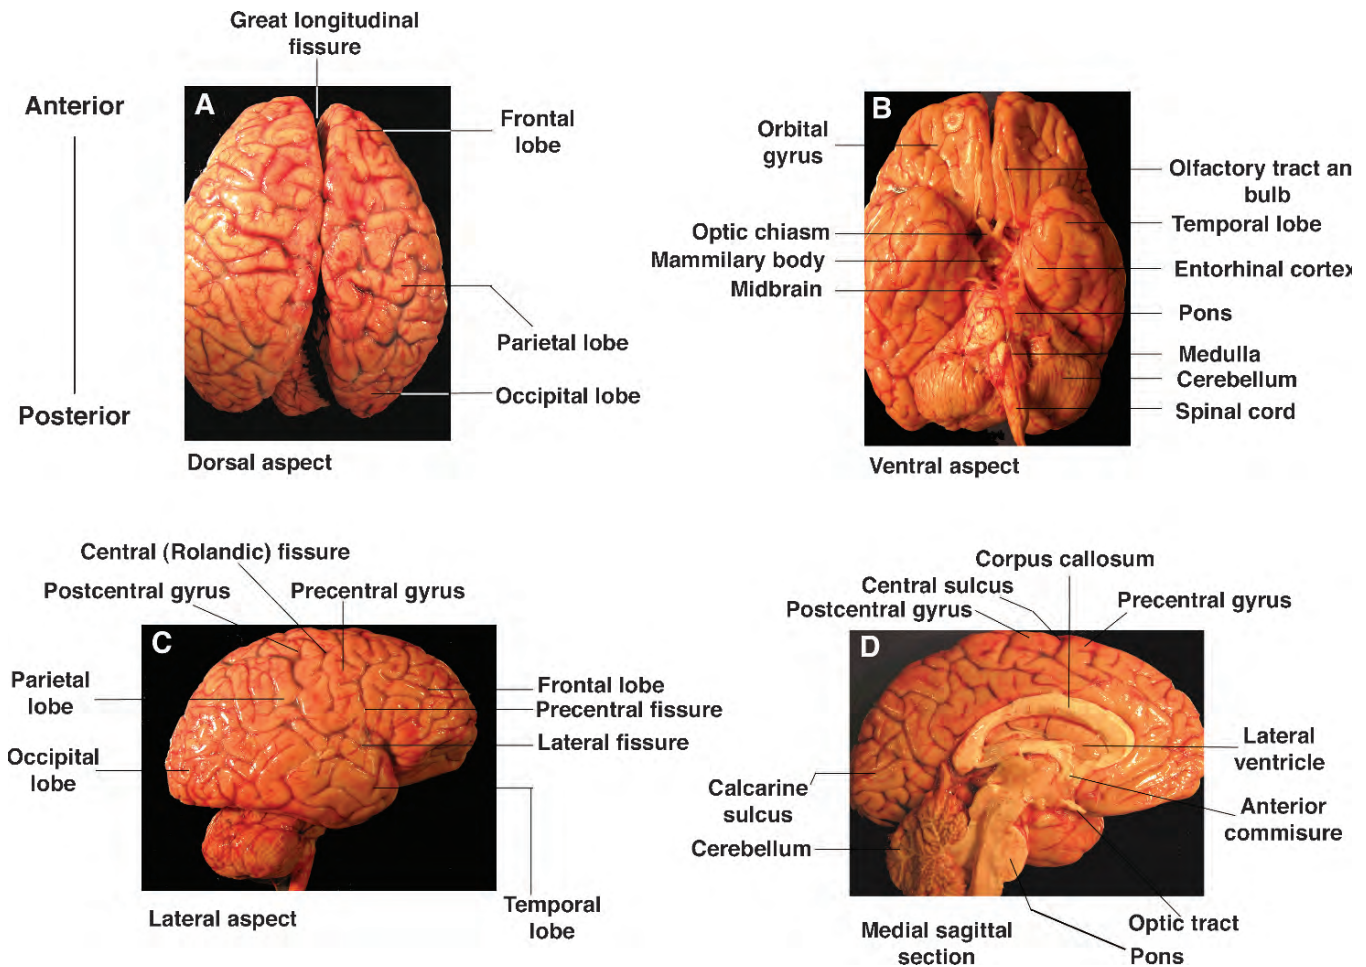

FIGURE 3.1. Gross external structures of the brain.

player of the homeostatic mechanisms that regulate the internal environment of the body.

3.2.1.2. *Cerebral Hemispheres*

The cerebral hemispheres are divided into two parts by the interhemispheric (sagittal) fissure. Interconnecting the two hemispheres is the corpus callosum (Martin, 1989) (Figure 3.1). The cerebral hemispheres have four major parts, which are the cerebral cortex, basal ganglia (or striatum), hippocampal formation, and amygdala (Figure 3.2). The human cerebral cortex is a highly convoluted structure. The elevated convolutions are known as gyri and the folds that separate the gyri are called sulci. The cerebral cortex includes the frontal, parietal, temporal, and occipital regions (Figure 3.1). In these regions the cerebral cortex usually has six layers. The frontal and parietal lobes are separated by the central sulcus (Rolandic sulcus) which separates two functional regions of the cortex namely the primary motor cortex which is located in the precentral gyrus and the primary somatosensory cortex which is distributed in the postcentral gyrus (Figure 3.1). The central sulcus extends from the longitudinal fissure along the midline ventrally almost into the lateral cerebral sulcus (Sylvian sulcus) (Figure 3.1). The frontal lobe, the largest of the cerebral lobes, extends from the central sulcus to the frontal pole. The function of the precentral gyrus is to integrate motor functions from different brain regions. The neurons are organized in a somatotopic manner, which means that different parts of the precentral gyrus are associated with distinct parts of the body both anatomically and functionally. Immediately anterior to the premotor cortex there are three parallel gyri, the superior middle and inferior frontal gyri. These areas involve processing of executive functions such as abstraction, thinking, cognition, language and emotion. In patients with AD and frontotemporal dementia (FTD), these areas are heavily damaged resulting in the characteristic profile of cognitive impairment typical of these patients. Part of the inferior frontal cortex (left side) includes Broca's motor speech area, an area important in the formulation of motor components of speech. The parietal lobes include the somatosensory cortex within the postcentral gyri (Figure 3.1). The remainder of the parietal lobe is divided into a superior and inferior lobes separated by the interparietal sulcus. The supramarginal gyrus and the angular gyrus divide the inferior parietal lobe, these regions receive input from the auditory and visual cortex and are involved in integration and discrimination of perception. Ventral to these gyri and extending into the temporal cortex is Wernicke's area; this structure is involved in language comprehension. While injury to Broca's area results in broken language, damage to Wernicke region results in difficulty understanding language.

The temporal cortex is situated inferior to the lateral sulcus and is divided into superior middle and inferior temporal gyri (Figure 3.2). On the inner aspect of the superior temporal cortex are the gyri of Heschl, which is the primary auditory region. The inferior portion of the temporal lobe is involved in vision

function and parts of the medial temporal lobe are involved in olfactory functions. The temporal lobe also includes the hippocampus and parahippocampal cortex. The hippocampus and amygdala are the second and third components of the cerebral hemispheres and are located under the cortical surface (Figure 3.2). The hippocampus is involved in memory formation while the amygdala modulates the action of the autonomic nervous system, hormone release and emotions. These two structures are part of the limbic system which includes the cingulate cortex as well as part of the diencephalon and midbrain. Together the limbic system plays a central role in the regulation of cognitive functions and mood. The occipital cortex or striate cortex is involved in integration of visual information.

The second major component of the cerebral hemisphere is the basal ganglia, which includes the caudate, putamen and globus pallidus (Figure 3.2). A white matter tract, denominated anterior commissure, divides the inferior aspect of the putamen and globus pallidus and separates the major cholinergic center in the brain also known as nucleus Basalis of Meynert or substantia innominata (Figure 3.2). The loss of cholinergic input in patients with AD is related to degeneration of this region, which is dependent on NGF for survival. The caudate and putamen are divided by the anterior capsule. The basal ganglia participate in control of movement but also have a role in behavior. In patients with Huntington's disease, this brain structure is severely affected.

3.2.1.3. *The Diencephalon*

Rostral to the brainstem lies the forebrain, consisting of the diencephalon and cerebral hemispheres (Crossman and Neary, 2005). The two sides of the diencephalon are separated by the lumen of the third ventricle, whose lateral walls they constitute (Figure 3.2). The diencephalon consists of four main subdivisions in a dorsoventral direction: the epithalamus, thalamus, subthalamus, and hypothalamus (Figure 3.2). The epithalamus is small and its most recognizable component is the pineal gland, which lies in the midline immediately rostral to the superior colliculi of the midbrain. The thalamus is by far the largest component of the diencephalon and it forms much of the lateral wall of the third ventricle. The thalamus plays an important role in sensory, motor and cognitive functions and has extensive connections with layers IV and V of the cerebral cortex. The thalamus is a central structure for relaying information to the cerebral hemispheres (Figure 3.2). The thalamus includes a large complex of nuclei that includes three principal nuclear masses (anterior, medial, and lateral) divided by the internal medullary lamina. Within the internal medullary lamina lie the intralaminar nuclei. On the lateral aspect of the thalamus, the reticular nucleus can be found. The hypothalamus forms the lower part of the walls and floor of the third ventricle (Figure 3.2). It is a highly complex and important region because of its involvement in many systems, most notably the neuro-endocrine system, the limbic system, and the ANS. From the ventral aspect of the hypothalamus in the midline emerges the infundibulum or pituitary stalk,

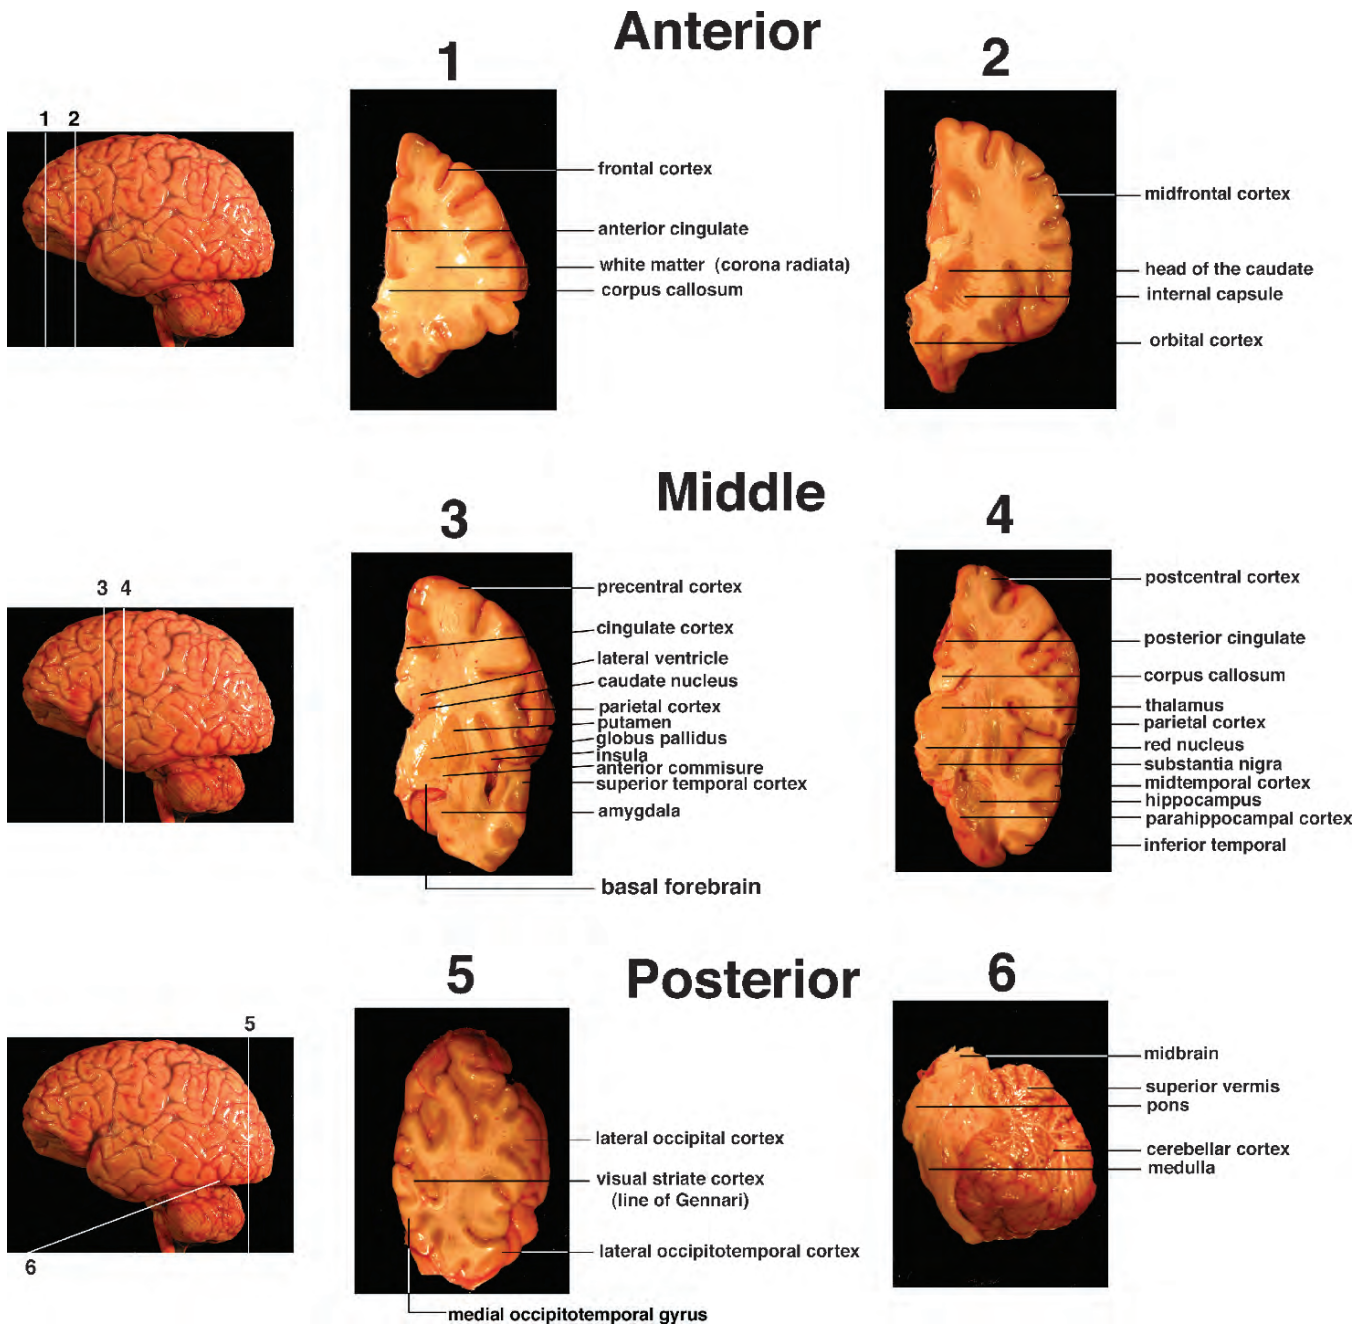

FIGURE 3.2. Gross internal structures of the central nervous system.

to which is attached the pituitary gland. The hypothalamus integrates the functions of the ANS and endocrine hormone release from the pituitary gland. The subthalamus is located under the thalamus and dorsal lateral to the hypothalamus it contains the subthalamic nucleus and the zona incerta. The subthalamic nucleus is connected to the globus pallidus and substantia nigra and is important in the control of movement. This circuitry is often affected in patients with PD and is amenable to surgical manipulation.

3.2.1.4. The Brainstem

The midbrain, pons, cerebellum, and medulla constitute the brainstem (Figure 3.2). The brainstem has three general functions. The first is to receive sensory information from cranial structures and to control muscles of the head. This function of the brainstem is similar to that of the spinal cord. The cranial nerves are constituents of the PNS that provide the sensory and motor innervation of the head and therefore are analogous

to the spinal nerves. The second is related to the fact that the brainstem contains neural circuits that transmit information from the spinal cord to higher brain regions and back. Finally, the integrated actions of the medulla, pons, and midbrain regulate the levels of awareness and arousal. This function is mediated by a diffuse collection of structures in the brainstem, denominated the reticular formation. In addition to these general functions, the various divisions of the brainstem provide specific sensory and motor functions. The medulla and the pons play a role in the vital regulation of the blood pressure and respiratory functions. The midbrain, also known as the mesencephalon, is divided into dorsal and ventral parts at the level of the aqueduct (Figure 3.2). The dorsal part is known as the tectum and includes the colliculi. The most ventral part of the midbrain tegmentum contains the substantia nigra, which consists of pars compacta and pars reticularis. The substantia nigra contains melanin pigmented neurons that produce dopamine. Degeneration of the substantia nigra is characteristic of patients with PD and results in disconnection between the midbrain and the caudo-putamen region. Other important structures contained in the midbrain are the oculomotor nucleus, the red nucleus, the periaqueductal grey and the medial lemniscus. Furthermore, the branches of the third cranial nerve emerge from the midbrain.

The pons (Figure 3.2) is further divided into ventral and dorsal sections. The ventral section contains the pontocerebellar fibers and the pontine nucleus. Corticospinal fibers run longitudinally. Other important structures in the pons include the locus ceruleus, which is main source of adrenergic fibers in the CNS. The neurons in the locus ceruleus are pigmented and produce epinephrine and norepinephrine. This brainstem structure is often affected in patients with AD, PD and depression. The medulla is divided into a caudal, mid, and rostral portions. The caudal portion includes the nucleus of the spinal tract of the trigeminal nerve. The mid portion of the medulla includes the nucleus gracilis and cuneatus as well as the decussation of the pyramids. The rostral medullary portion includes the inferior olivary nucleus which connects with the cerebellum. Damage to the pons and medulla is almost always life threatening.

The cerebellum regulates body movements, and may do so by controlling the timing of skeletal muscle contractions. The cerebellum and pons are considered together because they develop from the same portion of the embryonic brain. The cerebellum is attached to the brainstem by a large mass of nerve fibers that lie lateral to the fourth ventricle on either side (Figure 3.2). The cerebellum is divided into three sections by the inferior, middle, and superior cerebellar peduncles. These contain nerve fibers between the medulla, pons, and midbrain, respectively, and the cerebellum. The largest and most prominent is the middle cerebellar peduncle. The cerebellum consists of an outer layer of grey matter, the cerebellar cortex, surrounding a core of white matter. The cortical surface is highly convoluted to form a regular pattern of narrow, parallel folds or folia. The cerebellar cortex contains

three layers the outer or molecular, the Purkinje cells, and the inner granular layer. The cerebellar white matter consists of nerve fibers running to and from the cerebellar cortex. The white matter has a characteristic branching, tree-like arrangement in section, as its ramifications reach towards the surface. The cerebellum is involved with the coordination of movement.

3.2.1.5. *The Spinal Cord*

The spinal cord has the simplest organization of all six major divisions. It participates in the control of limb and trunk musculature, in visceral functions, and in the processing of sensory information from these structures. Also, it is a conduit for the flow of information to and from the brain. The spinal cord is the only portion of the central nervous system that has a clear external segmental organization, reminiscent of its embryonic and phylogenetic origins. The spinal cord is divided into the central thoracic lumbar and sacral segments. While in the cerebrum the gray matter is in the cortex and the white in the core, in the spinal cord the gray matter is central and the white is peripheral.

At cross section, the gray matter is the cord from the anterior and posterior columns, which contains the motoneurons and sensory neurons, respectively. An important feature of each spinal cord segment is the presence of a pair of roots (or associated branches or rootlets) called the dorsal and ventral roots. The dorsal roots contain sensory axons whereas the ventral roots contain motor axons. These sensory and motor axons, which are part of the peripheral nervous system, become mixed in the spinal nerves en route to their peripheral targets. The spinal nerves, which are also components of the peripheral nervous system, transmit sensory information to the spinal cord and motor commands to the muscles and viscera.

3.2.2. Internal Organization of the Central Nervous System

3.2.2.1. *Projection and Connections in the Brain*

The cerebral hemisphere and diencephalon have a more complex organization than that of the brainstem and spinal cord (Martin, 1989). The thalamus relays information from subcortical structures to the cerebral cortex via two different functional classes of nuclei; namely, those that are for relay and those that are for diffuse projection. Three of the four anatomical divisions of the thalamus serve relay functions (anterior, medial, and lateral nuclei) and one is a diffuse projection nuclei (intralaminar). Thalamic neurons send the axons to the cerebral cortex via the internal capsule, as do cortical neurons that project to subcortical sites. There are two major somatosensory pathways: the dorsal column of the medial lemniscal system, which mediates tactile, and vibration, and the anterolateral system, which mediates pain and temperature sense.

There are three other major somatosensory cortical areas, which include the primary, secondary, and tertiary somatosensory cortical areas and are somatotopically organized. The secondary somatosensory cortex and the posterior parietal cortex receive their projections from the primary somatosensory cortex and the posterior insular cortex receives input from the secondary somatosensory cortex. Corticocortical projections as well as callasol connections are made by neurons of layers two and three. Descending projections to the striatum, brainstem, and spinal cord originate from neurons in layer five, while projections to the thalamus originate from neurons in layer six.

Another important source of connectivity is that of the limbic system which includes the cingulate, hippocampus, and amygdala. The hippocampal formation is integrated by an infolding of the inferomedial part of the temporal lobe into the lateral ventricle along the choroid fissure. The dentate gyrus is distributed in between the parahippocampal gyrus and the hippocampus and contains a layer of granular neurons and the molecular layer, which receives connection from the entorhinal cortex and the parahippocampal gyrus. The hippocampal formation receives projections from the inferior temporal cortex via the entorhinal cortex and from contralateral fibers via the fornix. Efferent fibers merge on the ventricular surface of the hippocampus as the fimbria. The limbic system includes intrinsic as well as extrinsic connectivity. Connections between the entorhinal cortex and the molecular layer of the dentate gyrus (perforant pathway), Mossy fibers, CA1-CA4, and subiculum integrate the intrinsical connections. These structures are often affected in AD and are responsible for the short-term memory loss in this condition. The extrinsic limbic connections are between the cingulate gyrus, the hippocampal formation, the amygdala, and the septum, which in turn connect with the hypothalamus. Overall the limbic system network should be considered as functional units that include the prefrontal cortex, cingulate cortex, amygdaloid nucleus, limbic thalamus, nucleus accumbens, anterior hypothalamus, and raphe nucleus (Morgane et al., 2005).

3.2.2.2. *Laminar Organization of the Cerebral Cortex*

The cerebral cortex is the structure to which the dorsal column-medial lemniscal system projects and the origin of the corticospinal tract. It has a characteristic structure with neurons that are organized into layers. Different cortical regions contain characteristically different numbers of cell layers (Figure 3.3). Most of the cerebral cortex contains at least six cell layers, and this cortex is termed the isocortex (Figure 3.3). Because the isocortex dominates the cerebral cortex of phylogenetically higher vertebrates, it is also termed neocortex. In contrast to the isocortex, the allocortex contains fewer than six layers. Although present in higher vertebrates, the allocortex dominates the cortex of phylogenetically more primitive vertebrates. The phylogenetically oldest type of allocortex, the archicortex, constitutes the hippocampal formation and con-

tains three cell layers, which are the molecular, granular, and pyramidal. The paleocortex, thought to be a more advanced allocortex, is associated with areas that mediate olfactory function. The neocortex comprises the major sensory, motor, and association areas. Regions of neocortex that serve different functions have a different microscopic anatomy. Areas that regulate sensation have a well-developed layer IV. This is the layer to which most thalamic neurons from the sensory relay nuclei project. The primary visual cortex has this morphology. In contrast, the primary motor cortex has a thin layer IV and a thick layer V. Layer V contains the pyramidal neurons that project to the spinal cord, via the corticospinal tract. Association areas of the cerebral cortex, such as prefrontal and parietal association cortex have a morphology that is intermediate between those of sensory cortex and motor cortex. In summary, based primarily on differences in the thickness of cortical layers and on the sizes and shapes of neurons there are two types of cortex. The neocortex (or isocortex) has six layers; the allocortex has fewer than six layers and includes the archicortex of the hippocampus and the paleocortex of the olfactory regions.

3.2.2.3. *Neuronal Subtypes and Patterns of Interconnectivity*

The activity of the CNS depends on the complex patterns of connectivity among neurons and associated glial cells (Figure 3.4). The neurons are composed of a neuronal cell body, axons and dendrites (Figure 3.4A). The axons have a terminal end that constitutes the presynaptic site of the synapse. The dendrites have an apical site and multiple branches and spines. The connections among neurons are denominated synapses. Synapses occur between axons and dendrites, axons and cell bodies, and axons and axons. Neurons are excitatory and inhibitory. Excitatory neurons produce glutamate while inhibitory neurons produce GABA. Other neurotransmitters include acetylcholine as well as neuropeptides. Excitatory neurons are usually pyramidal (Figure 3.4A) and multipolar. Inhibitory neurons, also known as interneurons, are bipolar or pseudo-unipolar and contain calcium binding proteins such as calbindin (Figure 3.4B), parvalbumin and calretinin. Types of interneurons include the Martinotti cells, chandelier cells, double bouquet cells, giant basket cells, Cajal Retzius cells and bipolar cells. These sensory neurons receive information through dendrites and transmit that information to the ICNS via axon terminals (Siegel and Sapru, 2006). Retinal bipolar cells, sensory cells of the cochlear, and vestibular ganglia are included in this category.

Pseudo-unipolar neurons have a single process that arises from the cell body and divides into two branches. One of these branches projects to the periphery, while the other projects to the CNS. Each branch has the structural and functional characteristics of an axon. Information collected from the terminals of the peripheral branch is transmitted to the CNS via the terminals of the other branch. Unipolar neurons are relatively

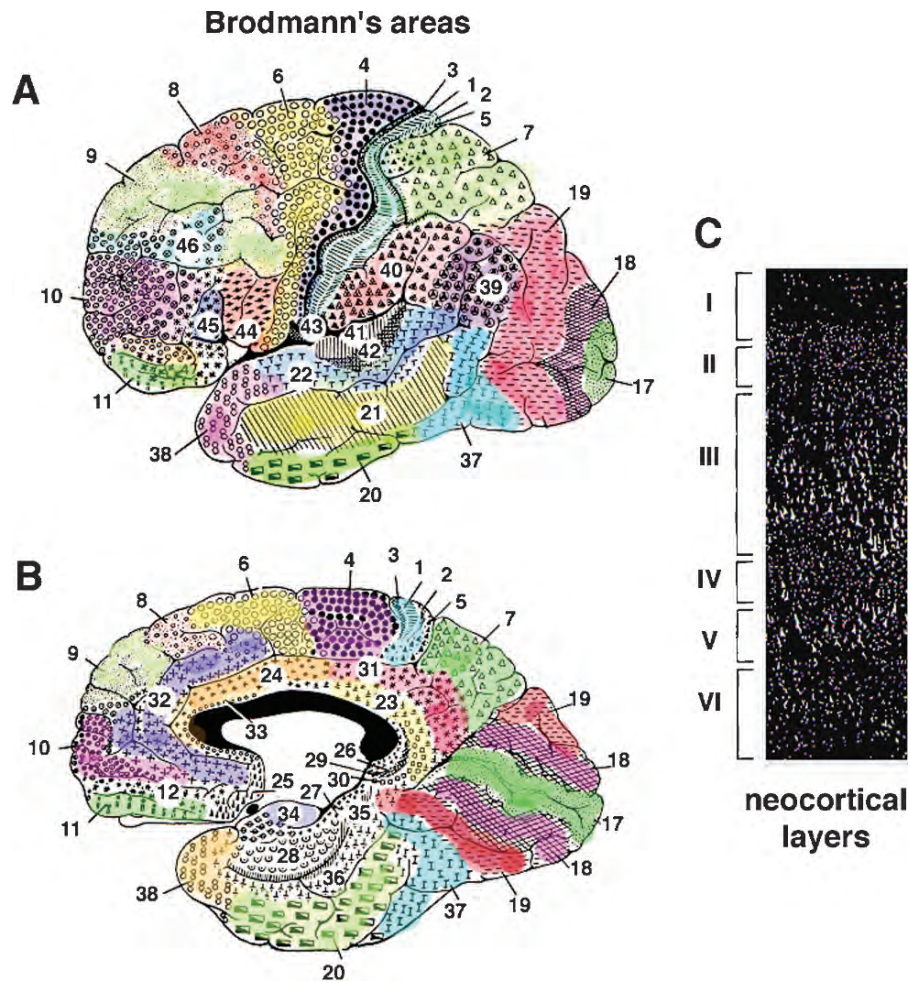

FIGURE 3.3. Diagrammatic representation of the neocortical layers and Brodmann areas.

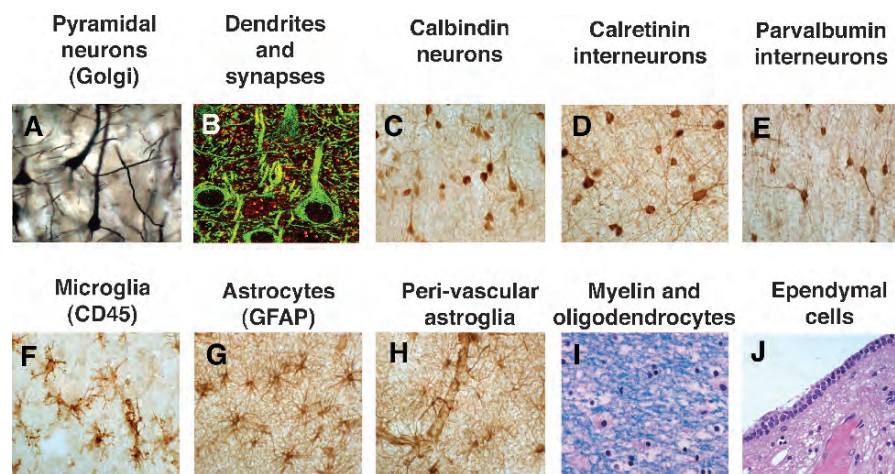

FIGURE 3.4. Cellular components of the central nervous system. (A) Neurons impregnated with Golgi silver satin, (C) Calbindin immunoreactive interneurons in the neocortex, (G) astrocytes immunoreactive with an antibody against GFAP, (H) peri-vascular astrocytes components of the BBB, (I) oligodendrocytes and white matter tracts stained with luxol fast blue, (F) ependymal cells around the periventricular zone.

rare in vertebrates. In these neurons, dendrites arise from the apical part of the cell body and axons form the base where the dendrites are located. Neurons can also be divided into principal or projecting neurons also known as type I or Golgi type I neurons. Principal neurons (e.g., motor neurons in the ventral horn of the spinal cord) have very long axons and form long fiber tracts in the brain and the spinal cord. Intrinsic neurons, also known as type II or Golgi type II neurons, have very short axons. These neurons are interneurons and are considered to have inhibitory function. They are abundant in the cerebral and cerebellar cortex.

3.3. Cerebrovascular Circulation

3.3.1. Blood Supply to the Central Nervous System

The cerebral hemispheres and diencephalon receive blood from the anterior and posterior circulations (Figure 3.5). The cerebral cortex receives its blood supply from the three cerebral arteries: the anterior and middle cerebral arteries, which are part of the anterior circulation, and the posterior cerebral artery, which is part of the posterior circulation. The diencephalon, basal gan-

glia, and internal capsule are supplied from branches of the internal carotid artery, the three cerebral arteries, and the posterior communicating artery (Crossman and Neary, 2005). The anterior and posterior systems are interconnected by two networks of arteries: (1) the circle of Willis, which is formed by the three cerebral arteries, the posterior communicating artery, and the anterior communicating artery, and (2) terminal branches of the cerebral arteries, which anastomose on the superior convexity of the cerebral cortex (Figure 3.5). The arterial supply of the cerebral cortex is provided by the distal branches of the anterior, middle, and posterior cerebral arteries. These branches are often termed “cortical” branches (Lee, 1995). The anterior cerebral artery originates at the division of the internal carotid artery, and courses within the interhemispheric fissure and around the rostral and dorsal surfaces of the corpus callosum.

The middle cerebral artery, which originates at the division of the internal carotid artery, passes through the lateral sulcus (Sylvian fissure) en route to the lateral convexity of the cerebral hemisphere, to which it supplies blood. The middle cerebral artery travels along the surface of the insular cortex, over the inner surface of the frontal, temporal, and parietal lobes, and appears on the lateral convexity. The posterior cerebral arteries originate at the bifurcation of the basilar artery, and each one passes around the lateral margin of the midbrain.

FIGURE 3.5. Gross external appearance of the circle of Willis and subarachnoid vessels.

The posterior cerebral artery supplies the occipital lobe and portions of the medial and inferior temporal lobe. The arterial supply of the spinal cord is derived from the vertebral arteries and the radicular arteries. The brain is supplied by the internal carotid arteries (the anterior circulation) and the vertebral arteries, which join at the pontomedullary junction to form the basilar artery (collectively termed the posterior circulation). The brainstem is supplied by the posterior system. The medulla receives blood from branches of the vertebral arteries as well as from the spinal arteries and the posterior inferior cerebellar artery (PICA). The pons is supplied by paramedian and short circumferential branches of the basilar artery. Two major long circumferential branches are the anterior inferior cerebellar artery (AICA) and the superior cerebellar artery. The mid-brain receives its arterial supply primarily from the posterior cerebral artery as well as from the basilar artery. The venous drainage of the spinal cord drains directly to the systemic circulation. By contrast, veins draining the cerebral hemispheres and brain stem drain into the dural sinuses. Cerebrospinal fluid also drains into the dural sinuses through unidirectional valves termed arachnoid villi.

3.3.2. Immune Cell Trafficking Through the Cerebral Vascular Network

The subarachnoid vessels penetrate the cortical structures and branch to produce the microvascular network which is in turn surrounded by the cellular components of the BBB through which immune cells may need to traffic (Figure 3.5B). The capillary endothelium of the BBB contains tight junctions that control the movement of leukocytes. In addition these cells are surrounded by a basement membrane and the processes of astroglial cells. The routes for trafficking of leukocytes into the nervous system are through the choroid plexus, subarachnoid space, and perivascular space (Ransohoff et al., 2003). In the first route, leukocytes migrate from the blood to CSF across the choroid plexus. In this pathway of migration, leukocytes travel across the fenestrated endothelium of the choroid-plexus, migrate through the stromal core villi, interact with epithelial cells of the choroid plexus and enter the CSF at its site of formation. This pathway is likely to be one route by which immune cells enter the CSF under physiological conditions using P-selectin and PECAM.

For the second route, leukocytes reach the CNS from blood to subarachnoid space. In this pathway, leukocytes travel from the internal carotid artery, across postcapillary venules at the pial surface of the brain into the subarachnoid space and the Virchow-Robin perivascular spaces. There, they might encounter cells of the monocyte/myeloid lineage that are competent for antigen presentation. The perivascular regions, where there is direct communication with the CSF compartment, are considered probable sites of lymphocyte-APC interaction and therefore, of immune surveillance of CNS. This pathway is also dependent on P-selectin.

The third pathway involves leukocyte immigration from blood to parenchymal perivascular space. In this third pathway, immune cells can enter the parenchyma directly, passing from internal carotids through the branching vascular tree of arterioles and capillaries and finally extravasating through postcapillary venules. In this case, leukocytes are required to cross the BBB and the endothelial basal lamina. Trafficking of activated lymphocytes across a resting cerebrovascular endothelium is a low-efficient event. This process is dependent on P-selectin, LFA-1 and ICAM (Greenwood et al., 2002).

3.4. Glial Cell Types

The supporting cells located in the CNS are called neuroglia or glial cells. They are relatively nonexcitable and more abundant. Neuroglia has been classified into the following groups: astrocytes, oligodendrocytes, microglia, and ependymal cells (Siegel and Sapru, 2006) (Figure 3.4). Astrocytes are the largest and have a stellate (star-shaped) appearance because their processes extend in all directions (Figure 3.4G). Their nuclei are ovoid and centrally located. The astrocytes provide support for the neurons, a barrier against the spread of transmitters from synapses, and insulation to prevent the electrical activity of one neuron from affecting the activity of neighboring neurons. Some transmitters (for example, glutamate and γ -aminobutyric acid [GABA]), when released from nerve terminals in the CNS, are taken up by astrocytes, thus terminating their action. The neurotransmitters taken up by astrocytes are processed for recycling. When extracellular K^+ increases in the brain due to local neural activity, astrocytes take up K^+ via membrane channels and help to dissipate K^+ over a large area because they have an extensive network of processes. Astrocytes are further divided into the following subgroups: protoplasmic astrocytes, fibrous astrocytes, and Muller cells. Protoplasmic astrocytes are cells present in the gray matter in close association with neurons. Because of their close association with the neurons, they are considered satellite cells and serve as metabolic intermediaries for neurons. They give out thicker and shorter processes, which branch profusely. Several of their processes terminate in expansion called end-feet. The neuronal cell bodies, dendrites, and some axons are covered with end-feet joined together to form a limiting membrane on the inner surface of the pia mater (glial limiting membrane) and outer surface of blood vessels (called perivascular lining membrane). The perivascular end-feet may serve as passage for the transfer of nutrients from the blood vessels to the neurons across the BBB (Figure 3.4H). Abutting of processes of protoplasmic astrocytes on the capillaries as perivascular end-feet is one of the anatomical features of the blood-brain barrier. Fibrous astrocytes are found primarily in the white matter between nerve fibers. Several thin, long, and smooth processes arise from the cell body; these processes show little branching. Fibrous astrocytes function to repair damaged

tissue, which may result in scar formation. Muller Cells are modified astrocytes present in the retina.

The oligodendrocytes are involved in the myelination process (Figure 3.4I). The oligodendrocytes present in the gray matter are called perineural oligodendrocytes. Oligodendrocytes are smaller than astrocytes and have fewer and shorter branches. Their cytoplasm contains the usual organelles (e.g., ribosomes, mitochondria, and microtubules), but they do not contain neurofilaments. In the white matter, oligodendrocytes are located in rows along myelinated fibers and are known as interfascicular oligodendrocytes.

The microglia are the smallest of the glial cells and are involved in phagocytosis and neuroinflammatory response in the CNS (Figure 3.4F). These cells are probably derived from monocytes from the bone marrow. They usually have a few short branching processes with thorn-like endings. These processes arising from the cell body give off numerous spine-like projections. They are scattered throughout the nervous system. When the CNS is injured, the microglia become enlarged, mobile, and phagocytic. Ependymal cells consist of three types of cells: ependymocytes, tanycytes, and choroidal epithelial cells. Ependymocytes are cuboidal or columnar cells (Figure 3.4G) that form a single layer of lining in the brain ventricles and the central canal of the spinal cord. They possess microvilli and cilia. The presence of microvilli indicates that these cells may have some absorptive function. The movement of their cilia facilitates the flow of the cerebrospinal fluid (CSF). Tanycytes are specialized ependymal cells that are found in the floor of the third ventricle, and their processes extend into the brain tissue where they are juxtaposed to blood vessels and neurons. Tanycytes have been implicated in the transport of hormones from the CSF to capillaries of the portal system and from hypothalamic neurons to the CSF. Choroidal epithelial cells are modified ependymal cells. They are present in the choroid plexus and are involved in the production and secretion CSF. They have tight junctions that prevent the CSF from spreading to the adjacent tissue.

3.5. Brain Regions Linked to Neurodegeneration and Other Neurological Diseases

As the life expectancy of the human population continues to increase, the possibility of developing neuroinflammatory and neurodegenerative diseases has increased considerably during the past 50 years. Of the neurodegenerative disorders, Alzheimer's Disease continues to be the leading cause of dementia in the aging population. Traditionally, neurodegenerative disorders have been defined as conditions in which there is selective loss of neurons within specific regions of the brain accompanied by astrogliosis. However, in the past 20 years, we have learned that the pathological process leading to the disfunction of selected circuitries in the brain initiates with

damage to the synapses rather than with the loss of neurons. In fact, neuronal loss is a late event that is probably preceded by damage to axons and dendrites followed by shrinkage of the neuronal cell body and abnormal accumulation of filamentous proteins.

Therefore, the revised concept of neurodegeneration suggests that neuronal injury initiates at the synaptic junction and propagates throughout selected circuitries leading to neuronal dysfunction, which resolves in the classical clinical symptoms characteristic to each of the neurodegenerative disorders (Hashimoto and Masliah, 2003). For example, in Alzheimer's Disease, early damage to the synapses between the entorhinal cortex and the molecular layer of the dentate gyrus (perforant pathway) results in the short term memory deficits characteristic of this dementing disorder. Later on disconnection of the cortico-cortico fibers in the frontal, parietal, and temporal cortex results in more severe memory deficits, alterations in executive functions, and abstraction. Degeneration of connections between the nucleus basalis of Meynert and the neocortex results in attention and memory deficits usually associated with loss of cholinergic neurons. Other circuitries and neuronal populations are also affected in Alzheimer's Disease, illustrating the complexity of these disorders and the fact that the concept of single population is affected needs to be expanded to multiple populations. This is the case with several other disorders including Parkinson's Disease, where degeneration is not limited to the dopaminergic system but also involves the limbic system, the raphe nucleus, the insula, and other systems.

In response to injury, neurons produce adhesion molecules and trophic factors that recruit astroglial and microglial cells to participate in the process of repair. In addition, the microvasculature and other glial systems might also participate in the process. Thus, neurodegeneration is accompanied by astrogliosis, microgliosis, and microvascular remodeling. While astroglial cells initially produce trophic factors and cytokines that aid in tissue repair, eventually these factors could amplify the inflammatory response by increasing vascular permeability resulting in microglial activation, which in turn might lead to the production of more proinflammatory cytokines and chemokines. A critical balance between the repair and proinflammatory factors often determines the future rate and progression of the degenerative process.

The understanding of the mechanisms of neurodegeneration and inflammatory response in these neurological conditions has undergone a tremendous progress in the past 10 years. It is now generally accepted that small soluble misfolded protein aggregates denominated oligomers are responsible for the injury. So for example, in Alzheimer's Disease, A-beta protein oligomers might damage the synapses in the limbic system while in Parkinson's Disease, a-synuclein oligomers damage the axons in the striatum and cortical regions. While significant progress has been made in understanding the fundamental mechanisms for the neuronal injury, less is known about the reasons for the selective neuronal vulnerability characteristic to these neurological conditions.

Summary

The understanding of the gross and fine structure of the brain is of fundamental importance to elucidate how the nervous system works, how it interacts with other peripheral organs and tissues and how it responds to external stimuli. The main objective of this chapter will be to provide an overview to the structure and organization of the nervous system that is relevant to the understanding of the unique interactions between the nervous and the immune system and to elucidate the pathogenesis of AD, PD, HIVE and other neurodegenerative and neuroinflammatory disorders,†. The nervous system has a unique circulatory organization based on the flow of CSF, the microvasculature the BBB and the regulation of the blood flow by the neural activity that provides a series of mechanisms to selectively regulate interactions between the nervous system and trafficking cells from peripheral tissues. This chapter provides the structural framework for the better understanding of these interactions under physiological conditions and in neurological diseases and includes sections of gross anatomical structure of the brain, projections, cellular variety, and cerebrovascular circulation.

Review Questions/Problems

1. Interconnecting the two hemispheres is the

- a. corpus callosum
- b. anterior commissure
- c. Rolandic fissure
- d. Sylvian fissure
- e. Precentral gyrus

2. The central fissure divides the

- a. visual cortex
- b. sensory and motor cortex
- c. limbic system
- d. brain stem
- e. cerebellum

3. Correlate the brain regions with the neurotransmitter

- a. acetyl choline _____
Neocortex, hippocampus
- b. glutamate _____
Locus ceruleus
- c. norepinephrine _____
S. Nigra
- d. dopamine _____
Basal forebrain

4. Correlate the brain region with the disease

- a. Parkinson's disease _____
Neocortex, hippocampus, basal forebrain

- b. Alzheimer's disease _____
Basal Ganglia
- c. Huntington's disease _____
S. Nigra
- d. Aphasia _____
Broca's Area

5. The primary auditory cortex or gyri of Heschl is located in the

- a. frontal lobe
- b. parietal lobe
- c. occipital lobe
- d. temporal lobe
- e. brainstem

6. The middle cerebral artery irrigates the

- a. fronto-temporal cortex
- b. visual cortex
- c. brainstem
- d. cerebellum

7. Neurons that produce GABA are also known as

- a. pyramidal cells
- b. inhibitory interneurons
- c. microglia
- d. astrocytes

8. The perforant pathway connects the

- a. entorhinal cortex with the forebrain
- b. hippocampus with the hypothalamus
- c. entorhinal cortex with hippocampus
- d. cerebellum and brainstem
- e. hippocampus and midbrain

The Blood Brain Barrier

William A. Banks

Keywords Active transport; Adsorptive endocytosis and transcytosis; Brain endothelial cell; Cytokine; Endothelin; Facilitated diffusion; Immune cell; Neurovascular unit; Transmembrane diffusion

4.1. Introduction

The blood-brain barrier (BBB) is intimately involved in regulation of the neuroimmune axis. It first prevents the unrestricted mixing of the fluids of the central nervous system with the blood. It then selectively regulates the exchange of cells, cytokines, and other solutes between the central nervous system and the blood. This regulatory aspect of the BBB is accomplished through various mechanisms and is itself affected by neuroimmune physiological and pathophysiological phenomena. This chapter will explore the intimate connections between the BBB and other components of the neuroimmune axis.

4.2. Development and Structure of the Blood-Brain Barrier

Evidence for an interface between the circulation and the central nervous system (CNS) dates back to the end of the nineteenth century (Bradbury, 1979). The best known of those early studies were done by a young Paul Erlich who found that some dyes did not stain the brain after their peripheral injection. Erlich concluded erroneously that the lack of staining was because these dyes did not bind to brain tissue. Several decades later, Goldmann, a student of Erlich's, found that these dyes could stain the brain when injected intravenously. Thus, these dye studies were reinterpreted as evidence in favor of some sort of barrier between the CNS and blood.

The location and nature of that barrier was controversial through much of the twentieth century. Elegant studies by Davson and colleagues identified the barrier at the vascular level. However, alternative opinions were held until classic studies were conducted with the electron microscope by Reese

and co-workers in the late 1960s (Reese and Karnovsky, 1967; Brightman and Reese, 1969). Previous work had shown no difference between vascular beds of peripheral tissues and the CNS when studied grossly or at the light microscope level. However, Reese and co-workers found numerous ultrastructural differences. These included a much-reduced rate of pinocytosis and an absence of intracellular fenestrations. The most widely discussed finding, however, is the presence of tight junctions between adjacent endothelial cells. The tight junctions, low rate of pinocytosis, and low number of intracellular fenestrations effectively eliminate capillary gaps and pores. This, in turn, essentially eliminates the production of a plasma-derived ultrafiltrate and hence the leakage of serum proteins into the brain.

From this single change, the lack of a production of an ultrafiltrate, evolves a large number of consequences for CNS function. Obviously, it is the basis of the restriction of protein access, which first defined the BBB in late nineteenth century. The need for an efficient lymphatic system is eliminated, but the lack of a lymphatic system means that the CNS needs other methods to rid itself of the free water and wastes produced by metabolism and the secretions of the choroid plexus. Without production of an ultrafiltrate, the CNS depends on other methods to extract nourishment from the blood. The BBB addresses this need with a large number of selective transporters for substances from electrolytes to regulatory proteins (Davson and Segal, 1996e; Davson and Segal, 1996d). Because the CNS is not equipped to handle an ultrafiltrate, its reintroduction, as with hypertensive crisis, can result in increased intracranial pressure and encephalopathy (Al-Sarraf and Phillip, 2003; Johansson, 1989; Mayhan and Heistad, 1985).

4.2.1. Components of the BBB

The BBB is not a single barrier, but several barriers, which are in parallel. This contrasts with the testis-blood barrier, which consists of several barriers in series. The most studied of these barriers is the vascular barrier and perhaps the least studied are the barriers, that interface between the circumventricular organs (CVO) and the rest of the CNS.

4.2.1.1. Vascular BBB

The vascular BBB occurs because of the modifications noted by Reese and co-workers in the endothelial cells, which comprise the capillary bed and line the venules and arterioles of the CNS. It is likely that these three regions are highly specialized. For example, immune cells primarily cross at the venules and most of the classic transporters are located at the capillaries (Engelhardt and Wolburg, 2004). No CNS cell is more than about 40 μm from a capillary. This means that a substance, that can cross the vascular BBB can immediately access the entire CNS. Substances that cross the vascular BBB can be either flow-dependent or not dependent on flow rate. A flow-dependent substance is one in which the BBB extracts from the blood nearly the maximal amount possible (Kety, 1987). The only way to increase the amount of the substance entering the brain is to increase the flow rate to the brain. Glucose is an example of a flow-dependent substance (Rapoport et al., 1981). A brain region that is particularly active has its increased demand for glucose met by an increase in regional blood flow. In contrast, transport of a cytokine such as tumor necrosis factor (TNF) is not flow dependent. Only a small percent of the TNF in blood is extracted by brain via the saturable transporter for TNF located at the BBB (Banks et al., 1991). Alterations of blood flow within physiological limits do not alter the uptake of TNF from blood by brain. However, extreme changes in the rate of blood flow or capillary tortuosity can result in rheological changes, such as the loss of laminar flow. Such alterations likely occur in stroke, AIDS, and Alzheimer's disease (de la Torre and Mussivand, 1993; Nelson et al., 1999). This may result in impaired permeation of flow-dependent and non-flow dependent substances.

4.2.1.2. Choroid Plexus

The choroid plexus are bags composed of epithelial cells that project into the ventricles and contain a capillary plexus (Johanson, 1988). The capillaries do not have barrier function and so produce an ultrafiltrate, which fills the bag. The epithelial cells have tight junctions and so prevent the ultrafiltrate from entering the ventricular space. Unlike the capillaries, the epithelial cells of the choroid plexus have a high rate of vesicular turnover, which is responsible for the production of the cerebrospinal fluid (CSF). However, the CSF is not an ultrafiltrate, but a secreted substance. The choroid plexus also has many selective transport systems, some of which are specific to it or are enriched in comparison to the vascular BBB.

4.2.1.3. Tanycytic Barrier

The CNS of mammals contains seven regions of the brain where the vasculature does not fully participate in a BBB (Gross and Weindl, 1987). These regions have at least one side that faces a ventricle and so are termed circumventricular organs (CVOs). Together, they comprise about 0.5% of the brain by weight. Their capillaries allow the production of an ultrafiltrate and so their cells are in more intimate contact with the circulation.

They are known to play vital roles as sensing organs for critical peripheral events; for example, they act as emetic centers and are important in blood pressure modulation (Johnson and Gross, 1993; Ferguson, 1991). They can relay their signals to the rest of the brain by neurons, which project from them to distant brain regions or project to them from other brain regions. However, the mixing of their interstitial fluids with that of adjacent brain tissue has been shown to be limited in most studies (Peruzzo et al., 2000; Plotkin et al., 1996; Rethelyi, 1984). Diffusion through brain tissue is poor and this alone would tend to produce a limit to mixing within a few hundred microns of the CVO (Cserr and Berman, 1978; de Lange et al., 1995). However, most studies also find a physical barrier to diffusion. The epithelial cells, which line the ventricles form tight junctions when they are over CVOs, thus limiting CVO-to-CSF diffusion. A functional barrier also exists for the diffusion of substances from the CVO to the adjacent brain region (Peruzzo et al., 2000; Plotkin et al., 1996; Rethelyi, 1984). Recent work has shown that bands of tanycytes limit diffusion out of the median eminence to the adjacent arcuate nucleus.

4.2.2. Perinatal Development and Special Characteristics of the Neonatal BBB

The idea that the rodent perinatal BBB is not developed has been extensively revised over the last few decades (Davson and Segal, 1996b). Many of the differences in the BBB of developing and adult animals, which were ascribed to an immature brain, are now known to be adaptations to the altered demands of the CNS. For example, some amino acids enter the CNS of neonates more rapidly than the CNS of adults not because the BBB is defective, but because BBB amino acid transporters altered to favor their transport. The BBB is slave to the CNS and so the reason the BBB transports them more avidly is because they are in greater demand by a developing CNS. Most of these adaptations involve transporter mechanisms. In comparison, non-saturable passage is not altered with development (Cornford et al., 1982).

This theme of the BBB adjusting its transporter capabilities to serve the CNS is repeated throughout development, probably also with aging, and even in disease conditions. One of the most dramatic examples is the developmental loss of the mannose 6-phosphate receptor, which transports the enzyme β -glucuronidase across the BBB. Transport function is very robust in neonates but is absent in adult animals (Urayama et al., 2004). Transgenic mice that do not produce β -glucuronidase develop a mucopolysaccharidosis, which recapitulates Sly's disease (Sands et al., 1994). Because of the developmental differences in the BBB expression of the mannose 6-phosphate receptor, the brain disease of neonates but not of adults responds to the peripheral administration of glucuronidase (Vogler et al., 1999).

Work with marsupials show that their BBB is largely intact in what is essentially the *in utero* period (Dziegielewska et al., 1988). As reviewed elsewhere (Urayama et al., 2004), work by several other laboratories has repeatedly shown that not

only is the perinatal rodent BBB not leaky to albumin, but that the vascular space is smaller per gram of brain. Some evidence suggests, however, that the barrier may be more leaky to much smaller molecules such as sucrose.

There are other aspects of barrier function that also change with development. The tanyctic barrier between the median eminence and the arcuate nucleus develops after birth in the rodent (Peruzzo et al., 2000). This means the arcuate nucleus is very vulnerable to circulating neurotoxins during the neonatal period. For example, monosodium glutamate destroys the arcuate nucleus with resulting obesity when given intravenously to a neonate, but not an adult. The epithelial cells, which line the ventricles of the brain, have tight junctions even over non-CVO sites in neonates, but not adults. Thus, neonates have a CSF-brain barrier, which limits the diffusion of substances between brain tissue and CSF.

4.2.3. Concept of the Neurovascular Unit and Comparison to Peripheral Vascular Beds

The endothelial cell is an anatomical location of barrier function and of the various saturable transporters (Figure 4.1). Capillary beds from peripheral tissues have numerous intracellular and intercellular pores and fenestrations and high rates of pinocytosis that account for their leakiness. The brain endothelial cell engages in comparatively little pinocytosis, has few intracellular pores or fenestrations, and intercellular pores or gaps are eliminated because of tight junctions.

However, the brain endothelial cell does not function in isolation. The abluminal (brain side) of the capillary is encased in a basement membrane 40–80 nm thick. This membrane does not act as a barrier to molecules but may restrict viral-sized particles (Muldoon et al., 1999). It also holds pericytes in close approximation to the endothelial cell (Balabanov and Dore-Duffy, 1998). The pericyte may be a pluripotent cell and may also act in opposition to astrocytes (Deli et al., 2005). Astrocytes project endfeet that surround the capillary in what looks at the ultrastructural level like a mesh or netting. Astrocytes secrete substances that tend to encourage tight junction formation. Pericytes tend to oppose this action of astrocytes. All three of these cell types (pericytes, astrocytes, and endothelial cells) secrete a variety of substances, including cytokines, into their local environment (Fabry et al., 1993). This greater BBB complex is in further communication with other cell types in the CNS, most notably microglia and neurons. The microglia may, in turn, be at equilibrium with circulating macrophages (Williams and Hickey, 1995). Other immune cells also enter and exit the CNS at unknown rates and frequencies as influenced by yet to be determined factors. Clearly, secretions of prostaglandins, nitric oxide, and cytokines from each of these cells are important for intercellular communication and can influence endothelial cell permeability (Chao et al., 1994; Nath et al., 1999; Shafer and Murphy, 1997).

The concept of the neurovascular unit (NVU) emphasizes the interactive role that cells and events within the CNS and in the circulation play on BBB permeability, as well as the role that

the consequences of BBB permeability play on them. The concept of the NVU includes other factors long known to influence the penetration of substances across the BBB, such as degradation, sequestration, and serum protein binding. The encompassing concept of the NVU is particularly useful when considering the next section, the mechanisms of transport across the BBB.

4.3. Mechanisms of Transport Across the BBB

Substances can enter or exit the CNS by a variety of mechanisms. Some of these mechanisms are operational in both the blood-to-brain (influx) or the brain-to-blood (efflux) directions, whereas others are unidirectional.

4.3.1. Blood to CNS

Saturable and non-saturable modes predominate influx. Within each of these categories are a diverse number of mechanisms. These different mechanisms tend to favor certain groups or types of substances.

4.3.1.1. Non-Saturable Passage

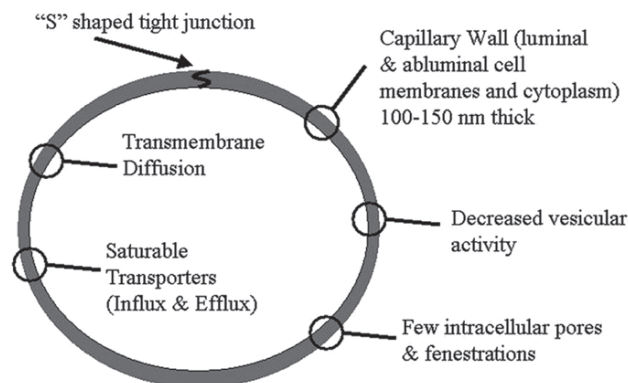

The hallmark of non-saturable passage is that the percent of material crossing into the CNS is not affected by the amount of material available for transport. The two main mechanisms of non-saturable passage are transmembrane diffusion and the extracellular pathways. The former is much better studied and its principles are widely applied by industry for the development of CNS drugs; the latter has received much less attention.

4.3.1.1.1. Transmembrane Diffusion

The major non-saturable mechanism by which small molecules cross the BBB is by membrane or transmembrane diffusion (Rapoport, 1976). The major determinant of passage is the degree to which the substance is lipid soluble. A substance that is too lipid soluble will be unable to repartition into the brain's interstitial fluid and so become trapped in the cell membranes of the BBB. A ratio of about 10:1 in favor of lipid vs aqueous solubility is near ideal for maximal passage across the BBB. The second most important determinant is molecular weight with passage being favored for smaller molecules. Other physicochemical determinants, such as charge, can occasionally become dominant for specific compounds. Many exogenous substances, including many drugs with CNS activity, enter the brain predominantly by way of transmembrane diffusion. Morphine and ethanol are prime examples of common substances, which cross the BBB by this mechanism (Oldendorf, 1974).

There seems to be no absolute molecular weight cut-off for transmembrane diffusion. A previous study, which had thought to define such an absolute limit had discovered, in retrospect, early evidence for an efflux system (Levin, 1980). The largest substance to date noted to have a measurable uptake by brain

The Brain Endothelial Cell

A BBB Complex

The Neurovascular Unit

FIGURE 4.1. The vascular blood-brain barrier: three levels of complexity. The upper panel illustrates the brain endothelial cell. This is the functional and anatomical site of both barrier function and of saturable and non-saturable mechanisms of passage. The major modifications allowing both barrier function and selective penetration of substances are indicated. The middle panel illustrates other cell types and structures important in BBB function. Pericytes are embedded in a basement membrane and astrocytes form a net-like structure over the capillary bed. Both cell types are in paracellular communication with the brain endothelial cells. Pericytes and astrocytes to some extent oppose each others effects on BBB functions. The lower panel illustrates the neurovascular unit, a concept, that emphasizes integration of peripheral, BBB, and central interactions.

by way of transmembrane diffusion is cytokine-induced neutrophil chemoattractant-1 (CINC1), with a MW of about 7.8 kDa (Pan and Kastin, 2001a). A surprisingly large number of small, lipid soluble compounds cross the BBB at a rate which is considerably greater or lesser than that predicted by their physicochemical characteristics (Oldendorf, 1971; Oldendorf, 1974). Binding to serum proteins and efflux systems are the major factors, that decrease influx and the presence of a saturable transporter is the major factor that increases influx.

4.3.1.1.2. Extracellular Pathways

Some protein is present in the CSF, showing that the BBB is not absolute. The amount of protein in CSF, however, is very small, being about 0.5%, or 1/200th, of that in plasma. The CSF is not an ultrafiltrate, but a secreted fluid. This means that the relative and absolute concentrations of proteins, electrolytes, minerals, and other substances can differ tremendously to that of plasma. The extracellular pathways are another avenue by which substances can enter the CNS (Balin et al., 1986; Broadwell and Sofroniew, 1993). These pathways represent what have sometimes been termed functional leaks at discreet areas of the brain, including the large vessels of the pial surface and subarachnoid space, the circumventricular organs, the nasal epithelium, the sensory ganglia of spinal and cranial nerves, and some deep brain regions, such as the nucleus tractus solitarius (Broadwell and Banks, 1993).

The amount of a substance that can enter the brain by the extracellular pathways is small. However, this route may be therapeutically relevant for compounds that have favorable peripheral pharmacokinetics, such as a long serum half-life and a small volume of distribution (Banks, 2004). Therapeutic antibodies and erythropoietin can access the brain by way of the extracellular pathways (Banks et al., 2004a; Banks et al., 2002; Banks et al., 2005a; Kozlowski et al., 1992) and this may underlie their therapeutic benefits (Alafaci et al., 2000; Ehrenreich et al., 2002; Erbyraktar et al., 2003; Morgan et al., 2000; Janus et al., 2000; DeMattos et al., 2002; Farr et al., 2003; Hock et al., 2003).

4.3.1.2. Receptor-Mediated and Saturable Transporters

Saturable processes represent a diverse group of mechanisms. Included in this group for purposes of discussion are two processes, which share some characteristics with the saturable systems: diapedesis and adsorptive endocytosis/transcytosis.

4.3.1.2.1. Active Transport vs Facilitated Diffusion

Saturable transporters (Yeagle, 1987) can be divided into those that require energy (active transport) and those that do not (facilitated diffusion). Both are dependent on a protein that acts as the transporter, may have co-factors, or be modulated by disease processes. Energy requiring systems can be unidirectional; that is, they may have only an influx or efflux component. Non-energy requiring saturable transport (facilitated diffusion) is bidirectional; that is, it transports substances in both directions with net flux being from the side of higher concentration to the side of lower concentration.

Most known saturable transporters at the BBB are facilitated diffusion systems (Davson and Segal, 1996c). For example, GLUT-1, the transporter for glucose, is a facilitated diffusion transporter. If the level of glucose is artificially raised above that of serum (or if radioactive glucose is introduced into the CNS, but not the serum), efflux of glucose can be shown.

4.3.1.2.2. Transcytotic vs Transmembrane Transport

Saturable transporters can also be categorized based on whether they use pores or vesicles to transport their ligands across the BBB. In the pore system, the molecule crosses from one side of the cell membrane to the other by passing through a cavity in the transporter protein. The substance is thus transported either into or out of the cytoplasm of the BBB cell; a second set of transporters on the opposing cell membrane completes the transfer across the BBB or the substance can rely on transmembrane diffusion. With vesicular transport, the transported substance binds to a receptor, invagination produces a vesicle, which is then routed to the opposite membrane, and the contents of the vesicle are released from the cell surface. Most small molecules, such as glucose and amino acids, use pores. Pore systems may be either active or facilitated diffusion systems. Vesicular transporters, on the other hand, are energy requiring and so are characterized by unidirectional transport. It is reasonable to assume that very large molecules would be required to use vesicles rather than pores to cross, but the molecular weight at which vesicles would be requisite is not known. It has been proposed that interleukin-2 (IL-2) is transported (Drach et al., 1996) by p-glycoprotein (P-gp). As P-gp is a pore system (Begley, 2004), IL-2 would be the largest substance currently known to be transported by a pore system. Peptides much smaller than IL-2 are known to cross by vesicular dependent pathways (Shimura et al., 1991; Terasaki et al., 1992). It is clear, then, that the size of the ligand alone does not dictate the need for vesicular transport.

4.3.1.2.3. Diapedesis of Immune Cells

A major shift in thinking about the relation of immune cells to the CNS and BBB has occurred over the last few decades. The CNS was once viewed as separate from the immune system and sterile in terms of immune cell occupancy except under conditions of brain infection. It is now clear that immune cells patrol the normal CNS, although the rate at which they enter and exit is not known. A major type of brain cell, the microglia, is known to be derived from peripheral macrophages, although the extent to which the pools of peripheral macrophages and microglia mix in the normal postnatal condition is unknown.

4.3.1.2.4. Adsorptive Endo- and Transcytosis

Adsorptive endocytosis occurs when a glycoprotein on the brain's endothelial surface binds another glycoprotein in ligand like fashion (Broadwell et al., 1988; Broadwell, 1989). This second glycoprotein (the ligand) may be free or attached to the surface of a virus or immune cell (Mellman et al., 1986). The binding can initiate endocytosis with the subsequent vesicle having several potential fates (Banks and Broadwell,

1994). In some cases, the vesicle is routed to lysosomes, the glycoprotein destroyed, and the vesicle rerouted to the endothelial cell surface for discharge of contents. In other cases, the vesicle can be routed to the Golgi complex and endoplasmic reticulum. In other cases still, the vesicle can be discharged at the endothelial cell surface opposite to that of uptake. In this case, the vesicle has crossed the width of the endothelial cell, and hence crossed the BBB, in a transcytotic event. What determines the fate of these vesicles is largely unknown, but at least some vesicles can engage in more than one fate (Broadwell, 1993). It may be that binding of a large amount of glycoprotein to the endothelial cell can overwhelm the lysosomal pathway and result in the vesicles being routed to the transcytotic or Golgi complex pathways.

Several principles of adsorptive endocytosis and transcytosis are clear. Many of the glycoprotein ligands are toxic and endocytosis may represent a mechanism to rejuvenate or repair the membrane (Raub and Audus, 1990; Vorbrodt and Trowbridge, 1991; Westergren and Johansson, 1993). Many viruses co-opt adsorptive endocytosis mechanisms to invade and infect brain endothelial cells and adsorptive transcytosis to invade the brain (Marsh, 1984; Chou and Dix, 1989; Schweighardt and Atwood, 2001). These processes may also be related to diapedesis as many of the events of immune cell passage across the BBB resemble these endocytic mechanisms. For example, both LFA-1 and ICAM, important to immune cell passage across the BBB, are glycoproteins. Although adsorptive endocytosis is in some sense saturable because of a finite amount of any single glycoprotein on a cell surface, it is not easy to demonstrate classical saturable kinetics for this process. In fact, excess glycoprotein can sometimes further stimulate endocytosis and so lead to a paradoxical increase, rather than decrease, in the rate of passage across the BBB (Banks et al., 1997). Glycoprotein distribution on brain endothelial cells is polarized; that is, a glycoprotein may be enriched on either the luminal or abluminal membranes (Vorbrodt, 1994; Zambenedetti et al., 1996). The tight junctions act as a fence to keep the glycoproteins confined to their respective sides of the endothelial cell (Deli et al., 2005). This means that the movement of a glycoprotein molecule (or a virus whose coat displays that glycoprotein) can be unidirectional as its transcytosis can only be initiated from the side of the brain endothelial cell, which contains the ligand's complementary glycoprotein (Villegas and Broadwell, 1993; Broadwell, 1989). The possession and distribution of glycoproteins similarly dictate which viruses can invade the brain; neurovirulent viruses, which invade the brain as free virus (as opposed to entering in Trojan horse fashion inside an infected immune cell) can do so because they possess a glycoprotein ligand capable of binding to the BBB.

4.3.2. CNS to Blood

Traditionally, passage in the brain-to-blood direction (efflux) has been neglected. However, efflux often accounts for the inability of otherwise effective drugs to accumulate in the

CNS. Pharmacogenomic studies have suggested that the individual variation in efflux mechanisms may explain why some individuals are less sensitive to the CNS effects of drugs or more sensitive to their toxicities (Lüscher and Potschka, 2002; Fellay et al., 2002). Efflux mechanisms are important to the homeostasis of the CNS, ridding the brain of toxins (Taylor, 2002). The rate of efflux can be, in addition to synthesis and degradation, an important determinant of the level of a substance produced within the CNS (Chen et al., 1997; Chen and Reichlin, 1998; Maness et al., 1998).

4.3.2.1. *Non-Saturable*

Efflux, like influx, has both saturable and non-saturable mechanisms. Transmembrane diffusion occurs for both influx and efflux. Other mechanisms, such as bulk flow, are unique for efflux.

4.3.2.1.1. Transmembrane Diffusion

Many of the principles that govern influx by transmembrane diffusion are also important in efflux. The dramatic role that efflux by transmembrane diffusion can play can be illustrated by comparing the fate of small, lipid soluble molecules to that of a protein after intrathecal administration. Intrathecal application of small, lipid soluble molecules, such as anesthetics, can have a local effect on spinal cord function but have little or no effect on the brain (Bernards, 1999). These substances readily cross the brain endothelial cell by transmembrane diffusion and do this as easily in the brain-to-blood direction as in the blood-to-brain direction. Therefore, they are cleared from the CSF before they are able to reach the brain (McQuay et al., 1989). In contrast, proteins such as leptin are too large and water soluble to undergo much transmembrane diffusion (LeBel, 1999; McCarthy et al., 2002). Leptin can reach the brain after intrathecal administration in amounts sufficient to produce effects on feeding through the hypothalamus (McCarthy et al., 2002; Shyng et al., 1993).

Efflux by transmembrane diffusion can also contribute to the poor diffusion of substances within brain parenchyma. Diffusion within the interstitial space of the brain is dependent on Brownian motion and the production of metabolic free water as driving forces and so is very slow (Cserr, 1984; Cserr and Berman, 1978). However, efflux by non-saturable (and saturable) mechanisms can further reduce the distance a substance will ultimately diffuse. For example, the less lipid soluble drug atenolol can diffuse about 3 times further into brain tissue than can the more lipid soluble drug acetaminophen (de Lange et al., 1993).

4.3.2.1.2. Bulk Flow and CSF Lymphatic Drainage

Bulk flow refers to the reabsorption of CSF into the blood at the arachnoid villi (Davson and Segal, 1996a). Any substance dissolved in CSF will enter the blood by this mechanism (Jones and Robinson, 1982; Pollay and Davson, 1963). In some cases, the levels of a substance in blood achieved after injection into

the CSF can be sustained longer and at higher levels than after an intravenous bolus (Maness et al., 1998; Chen and Reichlin, 1998; Chen et al., 1997). This is because the central injection acts similarly to an intravenous infusion, slowly delivering drug to the blood. CSF drains from the brain at the level of the cribriform plate into the cervical lymphatic system (Widner et al., 1987; Yamada et al., 1991). This may be the dominant route for CSF drainage at normal CSF pressures (Boulton et al., 1999). This can provide a direct route from the CNS to the cervical lymphatics (Oehmichen et al., 1979), as has been illustrated for gp120, the glycoprotein of the human immunodeficiency virus, HIV-1 (Cashion et al., 1999). This route to the lymphatics may explain why substances injected into the brain can produce a different immune response than when the substance is injected peripherally (Cserr and Knopf, 1992; Knopf et al., 1995).

4.3.2.2. *Saturable Transport*

The last decade has seen a huge increase in the interest of efflux by saturable mechanisms. Just as efflux by transmembrane diffusion can limit diffusion of a substance within the CNS, so can the presence of a saturable efflux transporter (Blasberg, 1977). Much of this interest centers around the multi-drug efflux transport systems (Begley, 2004), most notably P-gp. However, other efflux transporters for peptides, proteins, endogenous substances, and drugs are known to play important roles in physiology and disease (Drion et al., 1996; Martins et al., 1997; Mealey et al., 2001). For example, peptide transport system-1 is a major regulator of brain levels of methionine enkephalin, an endogenous opiate, that suppresses voluntary ethanol drinking (Plotkin et al., 1998). Depression and recovery of peptide transport systems-1 with ethanol drinking may relate to alcohol withdrawal seizures (Banks and Kastin, 1994; Banks and Kastin, 1989). IL-2 is currently the only cytokine known to be transported by a saturable efflux system; some have postulated this transporter may be P-gp. Poor accumulation of protease inhibitors, antibiotics, AZT, anti-cancer drugs and many other substances occurs because of efflux systems (Fellay et al., 2002; Glynn and Yazdanian, 1998; King et al., 2001; Lee et al., 1998; LÜscher and Potschka, 2002; Masereeuw et al., 1994; Spector and Lorenzo, 1974). Impaired efflux of amyloid β protein, the protein believed to cause Alzheimer's disease, develops with aging in mice which over-express amyloid precursor protein, thus promoting further accumulation within brain of amyloid β protein (Gherzi-Egea et al., 1996; Banks et al., 2003; Deane et al., 2004). Evidence suggests that impaired transport develops in humans as well and so may be a major mechanism for induction of Alzheimer's disease (Tanzi et al., 2004; Shibata et al., 2000).

4.4. Neuroimmune Interactions

The above discussion of BBB fundamentals is tailored towards understanding the role of the BBB in neuroimmune interactions. Below are specific examples of how the BBB is involved in neuroimmune interactions.

4.4.1. Receptors that are Expressed on BBB for Receptor: Ligand Interactions

An important distinction for understanding the function of the BBB is that of receptors vs transporters. The term receptor has undergone a transformation of its usage since its introduction in the late nineteenth century when it was first used to denote some physiological function. Eventually, the term receptor was used to denote a physical binding site through which a drug or hormone could exert its effects on a cell. In the 1980s, a distinction was made between receptor and binding sites, the former being coupled to intracellular machinery that translated its binding into a cellular effect. Binding sites on the brain endothelial cell can represent transporters, but they can also represent traditional receptors, that is, binding sites coupled to intracellular machinery. For example, brain endothelial cells have both insulin receptors and transporters. As a result, insulin is transported across the BBB to exert effects inside the CNS, but insulin also alters a number of functions of the brain endothelial cell. As examples of the latter, insulin alters the BBB transport of AZT (Ayre et al., 1989), tryptophan (Cangiano et al., 1983) and leptin (Kastin and Akerstrom, 2001) and alters brain endothelial cell alkaline phosphatase activity (Catalan et al., 1988). Many in vitro BBB studies have assumed that a binding site represents transporter function and many in vivo studies are so designed as to not consider whether receptors as well as transporters may exist at the BBB. However, a great deal of indirect evidence and some direct evidence indicates that the vascular BBB and the choroid plexus probably possess a large variety of receptors, which can alter BBB functions. Besides insulin, substances which bind to and alter the function of brain endothelial cells include mu opiate receptor ligands (Baba et al., 1988; Vidal et al., 1998; Chang et al., 2001), cytokines (Ban et al., 1991; Cunningham et al., 1992; van Dam et al., 1996; Vidal et al., 1998; Moser et al., 2004; Khan et al., 2003), leptin (Kastin et al., 2000; Bjorbaek et al., 1998), acetylcholine (Grammas and Caspers, 1991), adrenergics (Walsh et al., 1987; Kalaria and Harik, 1989), glutamate (Koenig et al., 1992; Krizbai et al., 1998), and chemokines (Sanders et al., 1998).

4.4.2. Permeability to Cytokines and Related Substances

The BBB is known to transport several cytokines in the blood-to-brain direction. For example, the BBB transports the IL-1's, IL-6, and TNF by three separate transport systems. Additionally, nerve growth factor, brain derived neurotrophic factor, interferons, neurotrophins, and leukemia inhibitory factor (Poduslo and Curran, 1996; Pan et al., 1997b; Pan et al., 1998b; Pan et al., 1998a) are also transported across the BBB. In some cases, the same gene which gives rise to a cytokine's receptor also produces the cytokine's transporter, whereas in other cases the receptor and transporter are immunologically distinct proteins (Banks and Kastin, 1992; Pan and Kastin,

2002). In general, transporters occur throughout the CNS, including the spinal cord, although the transport rate can vary greatly among CNS regions (Pan et al., 1998b; Pan et al., 2002; Banks et al., 1994; McLay et al., 1997). Enough cytokine is transported into the brain to affect CNS function. For example, IL-1 α crosses the BBB at the posterior division of the septum where it mediates cognitive impairments (Banks et al., 2001).

The cytokine transporters are not static but respond to physiological and pathological events. The transport rates of IL-1 and TNF each show diurnal variations (Pan et al., 2002; Banks et al., 1998b). The transport rate of TNF is altered in animals with experimental allergic/autoimmune encephalomyelitis (EAE), spinal cord injury, or blunt trauma to the brain (Pan et al., 1996; Pan et al., 1997a; Pan and Kastin, 2001b; Pan et al., 2003b).

4.4.3. Permeability to Other Neuroimmune Substances

Other substances with neuroimmune actions are handled by the BBB in a variety of ways. Monoamines are largely excluded by the BBB (Hardebo and Owman, 1990; Kalara et al., 1987) and opiates and opiate peptides as a rule enter the brain by transmembrane diffusion but are transported by saturable systems in the brain-to-blood direction (King et al., 2001; Elferink and Zadina, 2001; Banks and Kastin, 1990). Pituitary adenylate cyclase activating peptide, a member of the VIP/secretin/PACAP family, has immune functions (Arimura, 1992). Transport of its two major forms across the BBB is complex, involving both brain-to-blood and blood-to-brain components (Banks et al., 1993). Its blood-to-brain transport is altered with injury (Somogyvari-Vigh et al., 2000). Some of the other immune active substances whose passage across the BBB has been investigated are melanocyte stimulating hormone (Wilson et al., 1984), corticotrophin releasing hormone (Martins et al., 1996), and enkephalins (Banks et al., 1986; Elferink and Zadina, 2001).

4.4.4. Permeability to Immune Cells

As discussed above, immune cells cross the BBB by the highly regulated process of diapedesis. The mechanism by which immune cells cross the BBB has also been greatly clarified by recent work. Two major assumptions about how immune cells would enter the CNS have not withstood investigation. The first assumption was that immune cells would enter the CNS by leaking across a disrupted BBB. However, disruptions to the BBB are usually mediated by increased vesicular activity in the endothelial cells (Vorbrodt et al., 1995; Lossinsky et al., 1983; Mayhan and Heistad, 1985). These vesicles of 100 nm or so could not accommodate the passage of an immune cell 10,000 nm in diameter. Even in diseases where there is both increased immune cell trafficking into the CNS and a disrupted BBB, there is often a mismatch between the site of immune cell entry and BBB disruption (Engelhardt and Wolburg, 2004).

The second major assumption is that immune cells would cross between opposing endothelial cells taking the paracellular route. However, some cells favor a transcellular route. These immune cells tunnel through venular endothelial cells leaving the intercellular tight junctions intact (Wolburg et al., 2005). This tunneling process is complex and is initiated when LFA-1 on an immune cell binds to ICAM on the brain endothelial cell. Other paracellular messengers, which likely include cytokines, are then released (Male, 1995; Persidsky et al., 1997). Protrusions and invaginations of the endothelial cell and protrusions of the immune cell occur, with the immune cell possibly using the tight junction as an initial anchoring site (Lossinsky et al., 1991). Other ligands which have been postulated to play a role in this transcytotic process include PECAM, VE-cadherin, members of the JAM family and CD99 (Engelhardt and Wolburg, 2004). Some plasma inevitably accompanies the passage of the immune cell, which can give the appearance of a disrupted BBB (Greenwood et al., 1995; Avison et al., 2004; Persidsky et al., 2000).

4.4.5. Permeability to Viruses

Whether a virus is neurovirulent or not depends largely on its ability to cross the BBB (Chou and Dix, 1989). This should not necessarily be assumed, as viruses could induce neurotoxicity without themselves crossing the BBB by several mechanisms. For example, shed viral proteins might cross the BBB as could circulating cytokines whose release from peripheral sources was induced by the virus. However, most neurovirulent viruses seem to do their major damage directly after entering and replicating within the CNS. Some viruses can replicate within brain endothelial cells and are subsequently shed into the CNS (Cosby and Brankin, 1995). Other viruses invade the CNS by crossing the BBB (Nakaoke et al., 2005). Initial uptake by either route involves events reminiscent of adsorptive endocytosis as discussed above. Viral glycoproteins bind to brain endothelial cell (or choroid plexus) glycoproteins to initiate endocytosis. As with adsorptive endocytosis, the virus-containing vesicle is subsequently routed to various membrane systems, which can include discharge to the original side of uptake or transcytosis. Sialic acid and heparan sulfate are common components of the glycoproteins involved in viral uptake by the BBB (Schweighardt and Atwood, 2001; Banks et al., 2004c). In some cases, the functional glycoprotein is known. For example, rabies can bind to acetylcholine and nerve growth factor receptors (Schweighardt and Atwood, 2001). Without an appropriate luminal or basal glycoprotein with which to bind to the BBB cell, the virus is largely excluded from the CNS.

4.4.6. Secretion of Neuroimmune-Active Substances

The brain endothelial cells and the epithelial cells of the choroid plexus are capable of secreting a large number of

neuroimmune active substances. These include ILs (Fabry et al., 1993; Hofman et al., 1999; Reyes et al., 1999), TNF (Lee et al., 2001), nerve growth factor, (Moser et al., 2004), endothelin (Didier et al., 2002), monocyte chemoattractant peptide (Chen et al., 2001), nitric oxide (Mandi et al., 1998), RANTES (Simpson et al., 1998), and prostacyclin (Faraci and Heistad, 1998). Some of these substances are secreted spontaneously, and many of them can be stimulated with immunoactive substances such as lipopolysaccharide (LPS), bacteria, or viral proteins (Reyes et al., 1999; Vadeboncoeur et al., 2003; Hofman et al., 1999; Didier et al., 2002). The unique architecture of the BBB allows it to receive input from one of its surfaces and to secrete substances into the other. For example, LPS applied to the abluminal surface of brain endothelial cells in monolayer cultures will enhance release of IL-6 from the luminal surface (Verma et al., 2005).

4.4.7. Modulation of BBB Function by Neuroimmune Substances

Traditionally, neuroimmune modulation has been thought of in terms of disruption of the BBB. However, as the review above indicates, transporter functions are also vulnerable to manipulation by neuroimmune elements. Alterations in transport function are likely to be a more common event than disruption, as the latter is likely seen only with extreme pathology, whereas the former is likely a physiological, as well as a pathological, aspect of neuroimmune regulation. Other functions of the BBB, such as brain endothelial cell secretions, are also clearly affected by neuroimmune events.

4.4.7.1. Agents that Increase Permeability Through the BBB

Disruption was the first BBB function noted to be perturbed in neuroimmune disease. However, the review above makes it clear that an increase in the BBB permeability can be induced for specific agents by increasing their blood-to-brain transport rate or inhibiting their brain-to-blood efflux rate.

4.4.7.2. Regulation of BBB Integrity and Tight Junction Function

The classic example of BBB disruption is that seen in multiple sclerosis and the animal model of that disease, EAE (Pozzilli et al., 1988; Butter et al., 1991; Juhler et al., 1984). LPS and treatment with cytokines such as TNF have also been shown to induce BBB disruption (Megyeri et al., 1992). As discussed above, paracellular (through tight junctions) and transcellular mechanisms of transport exist. Although either can underlie BBB disruption, classic studies have shown that the major cause of increased protein leakage across the BBB for almost every kind of insult to the BBB or to the CNS is mediated by transcytotic mechanisms (Lossinsky et al., 1983; Vorbodt et al., 1995). Nevertheless, recent advances in understanding tight junction assembly and regulation have encouraged many

to investigate paracellular mechanisms. Both tight junction function and transcytosis are regulated events, although it is unclear to what extent protein leakage into the brain may be altered under physiological conditions. To some extent, paracellular and transcytotic routes likely involve some of the same cellular machinery, such as the cytoskeleton. TNF is known to induce rearrangements in cytoskeletal architecture. Additionally, cerebral ischemia, diabetes mellitus, and even intense pain are associated with alterations in the expression and cellular distribution of tight junction proteins and opening of the BBB (Brown and Davis, 2002; Chehade et al., 2002; Huber et al., 2002). The importance of regulatory processes in BBB disruption is vividly illustrated by the paradoxical finding that maximal disruption does not occur at the time of the CNS injury, even when the event is traumatic, but hours or days later (Baldwin et al., 1996). It is thought that it is the peripheral and central responses, such as cytokine release, to CNS injury rather than the CNS injury itself, which results in BBB disruption.

4.4.7.3. Regulation of Saturable Transporters

Regulation of both influx and efflux transporters are influenced by neuroimmune events. Additionally, cytokine transporters are also affected by various CNS events.

4.4.7.3.1. LPS and Blood-to-Brain Transporters

LPS increases the transport of cisplatin, insulin, and the HIV-1 viral coat glycoprotein gp120, but not of TNF or pituitary adenylate cyclase activating polypeptide (Banks et al., 1999; Minami et al., 1998; Nonaka et al., 2005; Osburg et al., 2002; Xaio et al., 2001). LPS affects leptin transport (Nonaka et al., 2004) through peripheral mechanisms and increases pituitary adenylate cyclase activating polypeptide binding to receptors on the BBB but does not alter transport. CNS injuries such as ischemia or trauma to the spinal cord induce a cascade of events, which can affect the transport of neuroimmune substances across the BBB as discussed below.

4.4.7.3.2. Cytokines and P-gp

Efflux systems are also altered by immune modulators. In vitro studies suggest that TNF and interferon gamma regulate P-gp (Theron et al., 2003; Stein et al., 1996). Interestingly, IL-2 appears to be both a substrate for P-gp and a modulator of its activity (Bonhomme-Faivre et al., 2002; Castagne et al., 2004; Drach et al., 1996). Because P-gp regulates the brain concentration of so many drugs and endogenous substances, immunomodulation could affect many other responses. For example, brain levels of exogenous opiate drugs such as morphine (King et al., 2001), endogenous opiates such as β -endorphin (Kastin et al., 2002), and neurotoxins such as cyclosporine (Sakata et al., 1994) would all be expected to be increased in patients given IL-2. Immunomodulation of efflux systems, therefore, could have a major effect on CNS metabolism and the response to drugs.

4.5. Role of BBB in Neuroimmune Diseases

The above review has emphasized BBB/neuroimmune interactions under normal physiological conditions. However, the BBB is intimately involved in neuroimmune diseases as well. The BBB can be a target of such disease, its functions may be adaptive to disease, or it can be a contributor to the disease process. Below are some examples of the ways in which the BBB is altered in diseases with neuroimmune processes.

4.5.1. TNF Transport and EAE

TNF has a biphasic effect on many neuroimmune processes, with too little or too much producing harmful effects (Pan et al., 1997c). TNF mediates many of its pathological effects through its central receptors and transport of circulating TNF is one source of CNS TNF (Gutierrez et al., 1993; Osburg et al., 2002; Pan and Kastin, 2002). Induction of EAE is partially dependent on TNF and IL-1 (Schiffenbauer et al., 2000). Immune cell invasion in general and during EAE in particular is dependent on TNF-modulated expression of ICAM and VCAM on brain endothelial cells and of LFA-1 on immunocytes (Male, 1995; Barten and Ruddle, 1994). Finally, the saturable transport across the BBB of TNF itself is greatly increased in EAE (Pan et al., 1996).

4.5.2. CNS Injuries and Cytokine Transport

As noted above, CNS injuries can produce a disruption of the BBB, but this disruption is temporally dissociated from the injury (Pan et al., 1997a; Baldwin et al., 1996; Banks et al., 1998a). This dissociation is because the disruption is the consequence of the reactions to injury rather than to injury itself. Not surprisingly, then, CNS injuries can also produce complex alterations in the BBB transport of cytokines. Besides the example of TNF in EAE given above, TNF transport is also increased in spinal cord injury (Pan et al., 1997a; Pan et al., 2003b; Pan and Kastin 2001b). This increase is neither confined to the site of injury, homogeneous throughout the CNS, nor related to the disruption pattern of the BBB (Pan et al., 2005; Pan et al., 1997a; Pan and Kastin, 2001b). It is also temporally and regionally independent of the changes in BBB transport rates of other cytokines and immunoactive substances whose transport rates are also altered with CNS injury (Banks et al., 1998a; Pan et al., 1998b). The pattern also is dependent on the type of CNS injury (Pan and Kastin, 2001b).

4.5.3. Antiretrovirals and the BBB

A major problem in treating viruses that can invade the CNS, such as HIV-1, is that antiretrovirals often cross the BBB poorly (Thomas, 2004). The major problem, however, is not that these substances are especially limited by their rate of transmembrane diffusion, but that they are nearly all substrates for efflux systems. For example, AZT is 16 times more lipid soluble than

sucrose and so should cross much more rapidly, but actually crosses at the same rate (Wu et al., 1998). AZT is a ligand for at least two efflux systems (Masereeuw et al., 1994; Takasawa et al., 1997; Wang and Sawchuck, 1995) and the protease inhibitors are all substrates for P-gp (Lee et al., 1998). P-gp is expressed by immune and other cells as well with three major phenotypic clusters in humans. Those with higher expression of P-gp, and therefore less able to accumulate protease inhibitors in tissues, are more resistant to treatment for HIV-1 (Fellay et al., 2002).

4.5.4. Immune Cell Invasion

Immune cell trafficking into the CNS is important in mediating neuroimmune diseases. Immune cell invasion is an early event in multiple sclerosis and EAE (Wolburg et al., 2005). Infected immune cells are a mechanism by which HIV-1 (Koyanagi et al., 1997; Nottet et al., 1996) and perhaps prions (Klein et al., 1997) invade the CNS.

Immune cell passage across the BBB is, in turn, affected by immune modulators. LPS and the HIV-1 immunoactive protein Tat increase expression by brain endothelial cells of ICAM and VCAM (Pu et al., 2003; Nottet et al., 1996) and monocytes treated with LPS have an increased rate of passage across the BBB (Persidsky et al., 1997). In vitro studies suggest that these events may be mediated through IL-1 β and IL-6 (De Vries et al., 1994).

4.5.5. Efflux of NeuroAIDS-related Proteins and Cytokines

Because the BBB prevents the effective accumulation of many of the antivirals, the CNS can act as a reservoir of virus. This reservoir could potentially reinfect the peripheral tissues. The CNS-to-blood movement of HIV-1 has not been investigated, but movement of two of its proteins has been. The coat glycoprotein gp120 is cleared by non-saturable mechanisms (Cashion et al., 1999). However, it has a propensity to be reabsorbed predominately by nasal drainage. As a result, it drains by way of lymphatic vessels directly to the cervical lymphatic nodes. If whole virus also takes this route, then that means that lymph nodes could be directly reinfecting without the virus having to enter the circulation where it could be exposed to antiviral agents.

A CNS reservoir of virus could affect the peripheral immune system by a mechanism, which does not involve reinfection of peripheral tissues. Tat, like gp120, is also reabsorbed with the CSF into the blood by a non-saturable mechanism (Banks et al., 2005b). Proteins that are enzymatically resistant in blood, such as Tat, gp120, and cytokines, can achieve high levels in blood even when their only source is the CSF. Production of these proteins within the CNS with subsequent reabsorption with the CSF into blood could be a way in which CNS virus produces toxic effects at peripheral tissues.

To date, IL-2 is the only cytokine known to be transported from the brain to the blood by a saturable transporter (Banks

et al., 2004b). This transporter, along with binding to plasma proteins and robust degradation by the BBB or CNS, effectively prevents much IL-2 from entering the brain. Evidence suggests that this transporter is likely P-gp. P-gp activity is decreased with HIV encephalitis (Persidsky et al., 2000) and this could lead to blood-borne IL-2 entering the CNS. Chronic IL-2 administration induces stereotypic behaviors and is used in an animal model of schizophrenia (Zalcman, 2001; Zalcman, 2002). Therefore, an enhanced entry of IL-2 is one mechanism by which HIV-1 could induce behavioral changes.

Summary

The BBB intimately interacts with cells and their secretions that are in both the CNS and periphery. Some neuroimmune substances, exemplified by cytokines, can cross the BBB directly and also have direct effects on the BBB. The BBB is itself a source of neuroimmune substances and can receive signals from one side, for example the brain side, and release substances in response to that signal from its other side. The passage of immune cells across the BBB is a highly regulated event as is the passage of viruses and viral particles. Overall, the BBB is an important component of the neuroimmune axis and the only component, which is simultaneously physically in both the peripheral and central compartments of the neuroimmune system.

Review Questions/Problems

1. The major cell type comprising the vascular blood-brain barrier is:

- a. epithelial
- b. endothelial
- c. muscle
- d. adipose
- e. a and c

2. Characteristics of the vascular blood-brain barrier are:

- a. tight junctions
- b. increased vesicular activity in the blood-to-brain direction
- c. a reduced number of saturable transport systems
- d. a and b
- e. a and c
- f. b and c

3. The neurovascular unit:

- a. would not include circulating immune cells or their products
- b. would include circulating immune cells and their products
- c. would exclude pericytes
- d. is primarily concerned with vagal control of cerebral blood flow
- e. is not relevant to mammalian physiology

4. Current evidence best supports a model by which immune cells cross the BBB by:

- a. crossing a blood-brain barrier that is already disrupted
- b. tunneling between brain endothelial cells (paracellular pathway)
- c. tunneling through brain endothelial cells (transcytotic pathway)
- d. occurs only in disease states
- e. a and d
- f. b and d
- g. c and d

5. Passage of substances from the CNS to the blood can occur by which pathway(s)

- a. transmembrane diffusion
- b. endocytosis by vascular epithelial cells
- c. with reabsorption of the cerebrospinal fluid
- d. a and b
- e. a and c
- f. b and c

6. Which statement is false about cytokines and the blood-brain barrier:

- a. a blood-to-brain saturable transport system has been described for IL-6
- b. cytokines can disrupt the blood-brain barrier
- c. cytokines are secreted by brain endothelial cells
- d. a hallmark of cytokine transporters is their lack of change with CNS diseases
- e. cytokines can cross the blood-brain barrier in amounts that can affect CNS function

7. Viruses can cross the blood-brain barrier

- a. by infecting immune cells which then cross the blood-brain barrier
- b. by crossing as free virus
- c. by first attaching to brain endothelial cell glycoproteins
- d. by first attaching to receptors on brain endothelial cells
- e. all of the above

8. P-gp is

- a. a blood-to-brain saturable transport system
- b. is a vesicular-mediated mechanism of crossing the brain endothelial cell
- c. has protease inhibitors as substrates
- d. does not transport opiate peptides
- e. is not modulated by IL-2
- f. all of the above

9. The major reason that the antiviral AZT has limited uptake by brain is:

- a. it is too lipid insoluble to cross by transmembrane diffusion
- b. it is a P-gp substrate

- c. it is too unstable in blood
- d. it is transported out of the brain
- e. it binds too strongly to immune cells

10. From the list below, the one largely excluded from the CNS by the BBB is:

- a. monoamines
- b. cytokines
- c. immune cells
- d. opiates
- e. viruses

Keywords ACAID; Autoimmunity; Immune deviation; Ocular immunology; Ocular inflammation

5.1. Introduction

The goal of this chapter is to introduce the immune response processes and mechanisms that occur in different compartments of the eye. This is done to explain the relationship between ocular anatomy and immunogenic inflammation, and to understand the consequences of ocular immune system's malfunction.

5.2. Anatomy and Physiology

The eye is an organ that transmits light from the surrounding environment onto the retina. The cornea, iris, and crystalline lens cooperate to form a focused image on the retina. The neurons of the retina capture the image and encode it for accurate transmission via the optic nerve to the visual centers in the brain. Figure 5.1 shows a horizontal cross-section of the human eye. Light entering the eye is refracted by the cornea and the crystalline lens, and is aperture-limited by the iris. The lens is suspended by a ring of thin fibers (zonules) that are attached to a membrane encapsulating the lens. Its refractive power can be adjusted by contraction or relaxation of a muscle ring called the ciliary muscle. This allows one to focus on an image as the object's distance from the observer varies.

The lens separates the anterior and posterior chambers. Thus, the eye contains 3 compartments: anterior chamber (AC), posterior chamber and vitreous cavity. The AC is a space between the iris and the cornea, which is filled with aqueous humor. On average, it is 3 mm deep, with a volume of about 250 μ L. The posterior chamber is also filled with aqueous humor; its location is posterior to the iris and ciliary body and anterior to the lens and the vitreous face. The largest compartment of the eye is the vitreous cavity, which is filled with vitreous gel. Its average volume is 6 mL. This compartmental division is a practical one. It is used extensively in clinical

practice of ophthalmology. Differential diagnosis of a large number of infectious and inflammatory disorders is based on the anatomic location of the process. It is also closely related to the main purpose of this chapter to describe the immune processes taking place in different compartments of the eye.

5.3. Anterior Chamber

5.3.1. Anatomy and Physiology

The cornea serves as the front part of the AC of the eye. Its exterior is covered by the precorneal tear film, which lubricates, nourishes and protects the corneal surface. The iris and the pupil represent the posterior border of the AC. The AC angle is an important structure which is comprised of: Schwalbe's line, Schlemm's canal and trabecular meshwork, scleral spur, anterior border of the ciliary body and the iris (Figure 5.2). Aqueous humor that fills the AC is produced by the ciliary epithelium located in the posterior chamber. The fluid flows through the pupil and is drained by the trabecular meshwork into Schlemm's canal and subsequently into the episcleral vessels. This passage is named *the conventional pathway*. Aqueous humor is also drained by *a uveoscleral pathway* across the ciliary body into the supraciliary space.

5.3.2. Anterior Chamber Associated Immune Deviation (ACAID)

The phenomenon of immune privilege was initially described by Dooremal in 1873 (van Dooremal, 1873). He noticed that tumor cells injected into the AC of the eye formed growing tumors unlike tumor cells injected into skin or other organs. Medawar discovered that transplants between genetically different individuals usually were destroyed due to the ability of the immune system to detect alien molecules on the graft. However, skin grafts placed in the AC of the eye and in the brain of rabbits survived much

longer. Medawar called the AC of the eye and the brain "immune privileged sites." In 1948 Medawar's fundamental work explained that immune privilege was a special circumstance where the laws of transplantation immunology did

not apply (Medawar, 1948). Immune privilege was defined as a prolonged, sometimes indefinite, survival of organ or tissue grafts at special body/organ sites (Barker and Billingham, 1977). Additional examples of such immune

privileged sites would be the cornea, lens, vitreous cavity, and subretinal space; testis, ovary, adrenal cortex, pregnant uterus, and certain tumors.

Anatomic structures were considered key elements of immune privilege in earlier studies. The existence of a blood-tissue barrier and the absence of afferent lymphatic drainage pathways led to the belief that antigens of the grafts placed in immune privileged sites remained physically sequestered from the immune environment. As such, the immune system never became aware of them. However, later studies demonstrated that the maintenance of immune privilege is actually a dynamic process combining immunoregulatory forces combined with anatomic structure to allow the survival of grafts in privileged sites (Nieder Korn et al., 1980; Nieder Korn 1990; Ksander and Streilein, 1993; Tompsett et al., 1990; Streilein, 1995). In other words, the blood-brain and blood-ocular barriers exist, but their creation and existence are actively maintained. The list of factors responsible for the ocular immune privilege is presented in Table 5.1.

It is now recognized that both active and passive factors of immune privileged sites contribute to their status. It has been known for over 100 years that the AC of the eye possessed qualities allowing a long-term survival of tissue and tumor grafts (van Dooremals, 1873). In the late 1970s Kaplan and Streilein discovered that antigenic cells placed into the AC were not only detected by the immune system, but also elicited a downregulation of alloimmune responses (Kaplan et al., 1975; Kaplan and Streilein, 1977).

It became clear that antigens are not physically sequestered from immune recognition in the AC, but that the consequence of their detection is a deviation from the expected immune response. Although AC injection of allogeneic lymphoid cells aroused the humoral arm of the immune response resulting in the production of antibodies against donor histocompatibility antigens, the cell-mediated component was impaired. Studies in the early 1980s led to the knowledge that a wide variety of antigens (alloantigens, tumor-specific antigens, soluble protein antigens, haptens, viral-encoded antigens) placed in the AC of mice produced a similar deviant pattern of systemic immune responses. Nieder Korn, Streilein, and Shadduck coined the term Anterior Chamber Associated Immune Deviation (ACAID) to designate this unusual response (Nieder Korn et al.,

1980). From multiple studies it became clear that ACAID is an antigen-specific systemic immune response to eye-derived antigens, a response that represents a selective deficiency of T cell functions that mediate delayed hypersensitivity to the antigen (Th1 cells), and B cells that secrete complement-fixing antibodies. However, this systemic immune response retains primed, clonally expanding cytotoxic T cell precursors and B cells that secrete IgG1, a noncomplement-fixing antibody. Lymphoid tissues of mice with ACAID contain three populations of regulatory T cells: CD8⁺ T cells suppressing expression of delayed hypersensitivity; CD4⁺ T cells suppressing the induction of Th1 cell responses; and CD8⁺ T cells that inhibit B cells from switching to IgG isotypes that fix complement.

In late 1980s experiments with samples of AC's aqueous humor showed that it possessed some immunomodulatory properties, but these properties were not global, i.e., aqueous humor does not inhibit all immune reactions (Kaiser et al., 1989). Suppression of the following phenomena by aqueous fluid was found:

1. Activated macrophage production of nitric oxide and reactive oxygen intermediate (Taylor et al., 1998).
2. Neutrophil-mediated lysis of target cells (Miyamoto et al., 1996).
3. Lysis of target cells by natural killer (NK) cells (Apte and Nieder Korn, 1996).
4. Conventional antigen-presenting cell (APC) activation of Th1-type cells in-vitro (Takeuchi et al., 1999).
5. C1q from binding to antibody-coated erythrocytes.
6. C3 cleavage to C3b via the classical or the alternative complement pathways (Goslings et al., 1998).

As we learn more about the ocular immunosuppressive environment, the list of immuneomodulatory molecules and factors within aqueous humor continues to grow.

Streilein and Kaplan have discovered that the spleen plays a crucial role in the immune deviation phenomena in rats (Streilein and Kaplan, 1979). This was confirmed in later experiments in mice (Streilein and Nieder Korn, 1981; Wilbanks et al., 1991). Following an injection of the heterologous protein antigen ovalbumin (OVA) into the AC, an ACAID-inducing signal (AIS) is released to the blood stream. For example, when naïve mice received intravenous injection of

TABLE 5.1. Factors responsible for ocular immune privilege.

Passive	Active: soluble factors	Active: cell-surface factors
Blood-tissue barrier	Transforming growth factor-β2	CD95 ligand
Tissue fluids drain IV	Alpha-melanocyte stimulating hormone	CD55, CD59, CD 46
Deficient lymphatics	Vasoactive intestinal peptide	
Reduced expression of major histocompatibility class I and II molecules	Calcitonin gene-related peptide	
Reduced antigen presenting cells with altered function	Somatostatin	
	Thrombospondin	
	Macrophage migration inhibitory factor	
	IL-1 receptor antagonist	
	Free cortisol	

blood from mice that had been injected with OVA into the AC 48 h prior, the naïve mice acquired OVA-specific ACAID. It was postulated that eye-derived antigen-bearing antigen presenting cells (APCs) escaped through the trabecular meshwork, and cells migrated via the bloodstream to the spleen. In the spleen the regulatory cells that mediate ACAID eventually emerged. These findings indicate that the eye contains nascent APCs that pick up the antigen and deliver it to the spleen via the blood. The spleen induces ACAID, without which, immune privilege in the AC cannot be sustained.

Further understanding of the ACAID phenomenon is attributed to Hara et al. who developed an in-vitro generated ACAID-inducing signal (Hara et al., 1992). These investigators incubated conventional APC (from peritoneal exudate) overnight in the presence of acid-treated aqueous humor and then pulsed with OVA. When injected into naïve mice these APCs induced ACAID. Since then, it became possible to perform experiments with ACAID-inducing APCs that could be grown in vitro. Takeuchi and Streilein conducted series of experiments that led them to conclude that ACAID-inducing APCs were formed by pulsing active-TGF β -2-pretreated-peritoneal-macrophages with OVA. The principal action of TGF-beta is to inhibit activation and proliferation of lymphocytes. It is a family of molecules named TGF β -1, TGF β -2 and TGF β -3. Cells of the immune system mostly produce TGF β -1. This family inhibits immunologic, inflammatory responses and has immunosuppressive effect. The above-mentioned APCs were capable of activating T-cell receptors (TCR) transgenic OVA-specific CD4 and CD8 T cells in vitro (Takeuchi et al., 1998; Takeuchi et al., 1999). It was found that a universal property of ACAID-inducing APCs created in vitro is the capacity to deviate naïve CD4+ and CD8+ T cells away from their typical differentiation pathway toward a pathway that might enable them to be regulators. Normal aqueous humor contains large amounts of thrombospondin (a glycoprotein involved in the clotting cascade). The gene controlling the formation of this protein is constantly active in ocular parenchymal cells. Thrombospondin and TGF β -2 may be the key players in creating immune deviation when antigens are introduced into immune-privileged sites.

Unique qualities of ACAID-inducing APCs have been analyzed by many researchers in order to understand their ability to alter the function of responding T cells (Takeuchi et al., 1998; Faunce et al., 2001; Masli et al., 2002). TGF β -2 treated peritoneal macrophages usually activate Th1 cells, and express normal levels of class I and II major histocompatibility proteins. However, TGF β -2 exposed APCs fail to upregulate CD40, and they secrete only small amounts of IL-12. IL-12 serves as a mediator and an inducer of innate immune responses to intracellular microbes. It also activates NK cells, promotes their cytolytic activity and development of Th1 cells. CD40 plays various roles in macrophage, dendritic cell, and endothelial cell activation. Expression of IL-12 and CD40 is not upregulated even in the presence of responding T cells. Interestingly, the supernatants of TGF β -2-treated APCs contain active TGF β -1, which is usually produced by bone-marrow-derived cells.

In addition, treatment with active TGF β -2 has a profound effect on the genetic arrangement of APCs, as discovered by a study of macrophage hybridoma #59, which is a laboratory-created cell line for immunologic studies (Wetzig et al., 1982). It is apparent that the thrombospondin gene is an early target of TGF β -2 and is upregulated. Thrombospondin has a number of actions that promote the ACAID-inducing properties of TGF β -treated APCs: 1) it binds to CD36 on APCs and tethers latent TGF β to the APC surface; 2) it binds to CD47 on APCs and on responding T cells, potentially forming a cellular bridge that stabilizes the APC/T cell interaction; 3) with CD47 on T cells, thrombospondin alters signaling through the TCR in a manner that deviates the cell's functional program; and 4) it promotes conversion of latent TGF β to its active form in the environment between APC and T cells.

As mentioned above, the spleens of mice that receive OVA into the AC acquire three populations of regulatory T cells. These cells are produced within seven days (Wetzig et al., 1982; Niederkorn and Streilein, 1983; Waldrep and Kaplan, 1983; Wilbanks and Streilein, 1990). One population is CD4+. When it is adoptively transferred into naïve recipients, it suppresses the induction of OVA-specific delayed hypersensitivity. A second population of regulatory cells is CD8+, which inhibits the expression of delayed hypersensitivity. So, generation of ACAID correlates with regulatory T cells that suppress the induction and expression of delayed hypersensitivity. A third population of regulatory CD8+ cells arises following AC injection of OVA. This population prevents OVA-specific B cells from class-switching their immunoglobulin isotype to the isotypes that fix complement: IgG2a, IgG2b, and IgG3. The second population of regulatory cells, efferent CD8+ T cells that suppress delayed hypersensitivity expression, has gained a lot of attention because of its uniqueness to ACAID. These cells are relatively easy to detect and evaluate. They can be evaluated systemically by transferring large numbers of spleen cells intravenously into mice previously sensitized to OVA and challenged for delayed hypersensitivity a few hours later. The regulator cells can be also evaluated locally in a "local adoptive transfer reaction" in which putative regulator cells are mixed with OVA-specific T cells and antigen, and the mixture is injected intradermally into the ear pinnae of naïve mice. Thus, researchers have been able to elucidate a mechanism of ACAID by demonstrating the production of T regulatory cells that inhibit the local expression of delayed hypersensitivity.

In order to induce immune deviation only two cells need to interact: the "tolerogenic" APC and the T cell. These two cells interact under the influence of innate immune cells within the lymphoid organs. It has been found that ACAID does not occur in the absence of gamma/delta T cells, (Skelsey et al., 2001; Xu and Kapp, 2001), natural killer T (NKT) cells (Sonoda et al., 1999), or B cells (D'Orazio et al., 1998a). The innate cells that have been most exclusively studied are the APC and NKT cells. The NKT cell is important in peripheral tolerance induction in association with the AC (Sonoda et al., 1999).

The antigen-transporting cells may direct the multicellular organization of the innate cells (specifically, NKT cell) with the appropriate adaptive immune cell precursors. The soluble factors secreted by the antigen-transporting cell recruit specific cell types and factors to create an immunosuppressive environment favorable to the induction of tolerance. The antigen that is injected into the AC is carried from the eye by the indigenous APCs. These transporting APCs are unique, possibly because they are bathed in eye-specific immunosuppressive factors that induce their special phenotype. It has been shown that the eye-derived macrophages selectively increased the chemokine MIP-2 (Faunce et al., 2001). While MIP-2 was previously thought to be a neutrophil chemoattractant, it was found that that MIP-2 was a strong chemoattractant for NKT cells as well. NKT cells are absolutely required for the development of the efferent T regulator cell in ACAID. When NKT cells were removed by use of antibodies *in vivo*, or when NKT deficient mice were used, the efferent T regulator cells were not generated (D'Orazio and Niederkorn, 1998b).

5.3.3. ACAID and Other Forms of Immune Regulation and Tolerance

Immunologic tolerance is defined as unresponsiveness to an antigen and it is induced by prior exposure to that antigen. When specific lymphocytes encounter antigens, three possible outcomes may follow: the lymphocytes are activated, leading to immune responses; the lymphocytes are inactivated or eliminated, leading to tolerance; or the antigen is ignored. Different forms of the same antigen may induce an immune response or tolerance or may elicit no response. Tolerance comes in many forms. Central tolerance ensures that the repertoire of mature lymphocytes cannot recognize ubiquitous self antigens, which are antigens most likely to be present in the degenerative lymphoid organs. This mechanism is mainly responsible for the elimination of self-reactive lymphocytes from the mature repertoire, and thus for self/nonself discrimination and therefore suppression of autoimmune disease. Peripheral tolerance, also called "active tolerance," is induced by recognition of antigens without adequate levels of the costimulators that are required for lymphocyte activation. T cell activation requires not only the recognition of antigen, but also the recognition of costimulators. These are also called "signal 2." If costimulators are not present while the antigen is being recognized, T cell anergy occurs. This also occurs in response to persistent and repeated stimulation by self-antigens in the peripheral tissues.

ACAID is a special form of peripheral tolerance. About 98% of the antigen that is inoculated into the eye is carried into the bloodstream within 6 h of injection (Wilbanks and Streilein, 1989). It was suggested that ACAID is just a manifestation of intravenously induced tolerance. However, ACAID was demonstrated to be distinctly different from intravenously induced tolerance. Intravenous tolerance is mediated by a CD8+ afferent T suppressor/regulator cell, and in intravenous tolerance

no regulatory efferent T cell is generated (Heuer et al., 1982). In ACAID, the afferent regulatory T cell is CD4+ and the efferent regulator is CD8+. Further, ACAID does not occur in mice that are deficient in NKT cells. Intravenously induced tolerance to the same antigens can be induced readily in NKT cell knockout (KO) mice (Sonoda et al., 1999).

Both ACAID and oral tolerance produce efferent CD8+ T regulator cells that are dependent on intact NKT cells. While low dose oral tolerance and ACAID correlate with the presence of efferent CD8+ regulatory cells, the cells are not functionally identical. The efferent T cells of oral tolerance respond to antigen by secreting IL-10 and TGF- β , whereas the efferent T suppressor cells of ACAID secrete TGF- β only (Weiner, 1997). However, NKT cells are needed for both forms of CD8+ T regulatory cell-mediated tolerance.

Can we learn whether ACAID is central or peripheral tolerance by examining the T helper cells that are involved? T helper cells were found to comprise two functionally distinct types (type 1 and 2) (Mosmann and Coffman, 1989; Mosmann, 1992). Th1 cells responded to antigen stimulation by secreting IL-1 and IFN γ . Th1 cells mediate delayed hypersensitivity reactions, and promote the switch of B cells to Ig isotypes that fix complement (IgG2a/b, IgG3 in mice). Th2 cells respond to antigen stimulation by secreting IL-4, IL-5, IL-6, IL-10, and IL-13, but they fail to secrete IFN γ . Th2 cells promote humoral responses rich in noncomplement-fixing IgG1, IgA, and IgE antibodies. Also, Th1 and Th2 cells are able to cross-regulate each other: Th1 cells suppressing Th2 cells and vice versa. Cross-regulation of Th1 and Th2 cells has been called "immune deviation." It was speculated that ACAID is a Th2 response evoked by an unusual route of antigen delivery (the eye). It has been reported that mice genetically deficient in IL-10 production fail to acquire ACAID (D'Orazio and Niederkorn, 1998). Some experiments dispute the idea that ACAID is a Th-2 mediated response (Streilein et al., 2001). It is currently thought that ACAID represents a unique form of tissue-dependent regulation of systemic immunity that resembles, but is mechanistically different from tolerance induced by some other routes and procedures. ACAID is a form of peripheral tolerance, unlike central tolerance, where clonal deletion and/or anergy occur within the thymus. Once induced, ACAID persists for a very long period of time. ACAID is an actively acquired and actively maintained manifestation of ocular immune privilege.

5.3.4. ACAID, Ocular Immune Diseases, and Implications for Therapy

ACAID may have either beneficial or deleterious effects on ocular inflammatory disease. Ocular inflammation that is elicited by Tcell-mediated delayed hypersensitivity and by complement fixing antibodies that impair or destroy vision. ACAID tries to protect the eye from such injury by selectively suppressing innate (production of phagocytic cells and

NK cells, blood proteins and cytokines) and adaptive (lymphocyte and antibody production) immune responses of the intense proinflammatory type (when large amounts of proinflammatory cytokines are present and are ready to excite inflammation). For certain infectious pathogens the entire array of immune defense mechanisms is mobilized in order to eliminate the exciting agent. If immune privilege and ACAID prevail, resistance to infectious agents cannot be mediated by delayed hypersensitivity T cells and by complement-fixing antibodies because these components are not active in such an environment. In this situation the eye faces a dilemma: whether to sustain immune privilege and prevent intraocular inflammation, thus risking the infection to ruin the eye, or withdraw immune privilege and kill the pathogen, but risk the eye destruction from uncontrolled inflammation.

Thus, immune privilege and ACAID could have both positive and negative effects in the eye. So what is the role of such a mechanism? ACAID might play a role in protecting the eye against autoimmune attack directed at strong ocular autoantigens such as arrestin, interphotoreceptor retinol binding protein, and rhodopsin.

Some speculate that ACAID-based immunotherapy may be beneficial in immune-mediated diseases of the eye and a variety of other organs. This is due to the fact that the immune deviation of ACAID produces T regulatory cells that are effective in inhibiting both Th1 and Th2 responses (both primary and secondary responses). Cd1d-reactive NKT cell-dependent tolerance or ACAID induced by inoculation of antigen into the eye may contribute to self-tolerance and prevention of autoimmune responses in organs and tissues in general.

There are reports of correlations of defective or deficient NKT cells in a number of autoimmune diseases in mice and humans (Sumida et al., 1995; Baxter et al., 1997; Wilson et al., 1998; Illes et al., 2000; Mieza et al., 1996; Zeng et al., 2000; Shi et al., 2001; Nagane et al., 2001). In humans, diabetes, systemic sclerosis, myasthenia gravis, and multiple sclerosis and in mice, a lupus model, are associated with NKT cell deficiencies. It was demonstrated that the adoptive transfer of NKT cells prevented diabetes in NOD mice. However, it is not clear whether the effectiveness of this treatment was actually due to the establishment of immune deviation of Tr cell-mediated active tolerance.

It is known that ACAID contributes to ocular tumor survival and long-term survival of orthoptic corneal allografts. Some experiments showed that removal of NKT cells prevented the continued acceptance of ocular tumors and caused the elimination of the immune privilege of the eye. Without functioning NKT cells, mice were not able to accept orthoptic corneal allografts for prolonged periods of time (Sonoda et al., 2002). This data demonstrates the essential role of NKT cells in the generation of ACAID. New information about ACAID may lead to application of ACAID mechanisms in prevention and treatment of immune-mediated inflammatory diseases in humans.

5.4. Retina

5.4.1. Anatomy

A more complete coverage of this topic appears in Chap. 11 of this book. In short, the retina is a thin transparent layered structure lining the posterior eye wall. The main cell types include photoreceptors (rods and cones), which capture the light; bipolar and ganglion cells, which pass the visual signal on toward the optic nerve, and horizontal and amacrine cells, which provide lateral interactions among cells in neighboring locations. Figure 5.3 demonstrates a diagram of cross-sectioned retinal layers (A), a preparation of normal donor retina (B), and tissue from a donor who suffered from a retinal degeneration, causing the disappearance of the photoreceptor layer (C).

The layers of normal cross-sectioned retina (from outer to inner retina) are:

- Retinal pigment epithelium (RPE) and its basal lamina
- Rod and cone inner and outer segments
- Outer nuclear layer
- Outer plexiform layer
- Inner nuclear layer
- Inner plexiform layer
- Ganglion cell layer
- Nerve fiber layer
- Internal limiting membrane

A single layer of RPE cells fulfills the role of sustaining the metabolism of the photoreceptors: The metabolic level of the photoreceptor outer segments is among the highest in the human body. RPE cells supply nutrients and oxygen, regenerate phototransduction products, and digest debris shed by the photoreceptors.

Photoreceptors, the cells capturing the incoming light, come in two main classes: rods, whose high internal gain allows vision at very low light levels, and cones, in short, medium, and long wavelength types to allow color perception. In both classes of cells the actual light capture and conversion takes place in the outer segment—visible as a band with long/thin elements (rods) toward the left edge and shorter/stubbier elements (cones) in the center of Figure 5.3B. The cell's inner segment, located in the outer nuclear layer (ONL), provides the transduction to secondary neurons and regulates cell function.

The outer plexiform layer (OPL) contains the contacts between photoreceptors, horizontal and bipolar cells, allowing the first stage in retinal image processing to take place. This processing provides coupling between neighboring rods and/or cones, allowing for the smooth transition between rod and cone function during light/dark adaptation and for dealing with differences, and rapid changes, in local illumination. The inner nuclear layer (INL) contains the cone and rod bipolar cells. Cone bipolar cells form the first stage of image processing in the visual system, combining output from different cone types for color processing. In the periphery, they gather

information from multiple cones, and save image transmission bandwidth by reducing resolution. All rod bipolar cells receive input from multiple rods, allowing reliable signal processing at very low light levels. Also located in the INL are the cell bodies of horizontal and amacrine cells.

In the inner plexiform layer (IPL), extensive interactions take place through synaptic contacts: between bipolar cell axons and retinal ganglion cell dendrites; between rod and cone on-bipolar cells through rod amacrine cells (thus merging the rod output signals into the cone pathway); between amacrine, ganglion, and bipolar cells (providing inhibitory feedback to strengthen ganglion cell properties); and between bipolar cells and interneurons (performing a feedback function between neighboring bipolar cells).

The ganglion cell layer (GCL) contains the cell bodies of retinal ganglion cells, with their axons running across the retinal surface (nerve fiber layer) toward the optic nerve head, and on through the optic nerve to the lateral geniculate nucleus in the mid-brain. The inner retinal blood supply (outside the foveal avascular zone), the nerve fiber layer, and a thin membrane (the inner limiting membrane) form the most superficial retinal structures.

In addition to the neuronal cell types responsible for visual signal transmission the retina has several types of supporting cells, similar in function to the RPE cells supporting the photoreceptor outer segments. The most important of these are the Mueller cells, whose principal role appears to be to buffer and balance electrolyte concentrations in the extracellular space, in response to the activity of the retinal neurons, especially photoreceptors.

Figure 5.3C shows a cross-section of the retina, but this tissue came from a donor who had lost useful vision due to a retinal degeneration. There is a complete loss of photoreceptor outer segments, the almost complete absence of cells in the ONL (i.e., photoreceptor inner segments). However, the inner retinal cells are preserved in substantial numbers.

5.4.2. Anatomy and Physiology: Retino-Cortical Pathway

The eye and the central nervous system are connected through the fibers of the optic nerve. These fibers, with a diameter of about $1\mu\text{m}$, are actually the axons of retinal ganglion cells. Inside the eye, the fibers run along the retinal surface toward

FIGURE 5.3. A: Schematic representation of the cell layers in the retina. Light entering the retina passes through the nerve fiber (9), ganglion cell (8), inner nuclear (6)—containing bipolar cells (B), and outer nuclear (4) layers, before being absorbed in the outer segments of the rods (R) and cones (C). B: Cross-section through the retina near the fovea, showing healthy photoreceptor outer segments (POS), multiple layers of photoreceptor cell nuclei in the outer nuclear layer (ONL; labeled black), bipolar cell nuclei in the inner nuclear layer (INL) and ganglion cell bodies in the ganglion cell layer (GCL). C: Retina of a patient with a long history of retinal degeneration, and bare light perception in the last years of life, showing lack of photoreceptor outer segments and cell bodies in comparison with B. (Illustration from “Neuroprosthetics: Theory and Practice,” Chapter 17, 2004. Used with permission from World Scientific Publishing Co.)

the optic nerve head in a characteristic pattern, such that fibers of the upper and lower retinal halves remain separated, and fibers close to the horizontal meridian, but far from the nerve head, arc away from this line to allow room for fibers originating closer to the nerve head. This orderly arrangement causes the fibers from the foveal area (which form 15–20% of all nerve fibers) to be located in the temporal quadrant of the optic nerve, at least for the initial portion of its trajectory.

After the axons enter the optic nerve, each fiber is encapsulated with a myelin sheath, formed by a class of cells called oligodendrocytes; this sheath decreases the membrane conductance of the axons, increasing the conduction velocity and the length over which impulses can be conducted without severe attenuation. Only at the so-called Ranvier nodes is the myelin sheath interrupted, allowing the impulses to be reinforced by virtue of the gating properties of the local membrane.

A cross-section through the human visual pathways can be seen in Figure 5.4. One may note that the predominant pathway leads from the eye to the lateral geniculate nucleus (LGN) of the thalamus, and from there to the occipital part of the cortex, while less important numbers of fibers branch off to a tectal area, the superior colliculus (SC), and to a number of pre-tectal nuclei. We will briefly discuss these subcortical pathways below.

The LGN and cortical areas exist in duplicate in the two halves of the brain. Each deals with one half of the visual world: the optic nerves from the two eyes meet in a structure called the optic chiasm, where fibers from the two nasal retinas cross over to combine with those from the temporal retina of the fellow eye; consequently each LGN and cortical hemisphere receive visual information from two corresponding retinal halves on their own side, and thus from the contralateral half of the visual field.

The LGN has a layered structure, with layers devoted to nerve fibers coming from each eye, and subsequent pairs of layers receiving axons of different ganglion cell types. Significant interaction between layers does not occur; therefore, binocular interactions such as those required for stereopsis do not take place until the level of the visual cortex. The gateway function of the LGN, which in other mammals such as the cat appears to play a crucial role in adaptation and attention, and through which signals from the two eyes can mutually inhibit each other, is thought to be less prominent in primates, including humans. Yet anatomical feedback connections from a number of subcortical nuclei onto the LGN are as extensive in monkey as in cat, and gating functions related to circadian rhythms and other systemic conditions is therefore plausible in primates as well.

FIGURE 5.4. Structure and location of the human primary visual pathways, in relation to other major brain structures. The left cerebral hemisphere, with the exception of the occipital cortex, has been removed; the left LGN is hidden by the optic radiations (arrow). (Illustration from "Neuroprosthetics: Theory and Practice," Chapter 17, 2004. Used with permission from World Scientific Publishing Co.)

Forward pathways from the LGN lead to the primary visual cortex (V1, also called striate cortex; these fibers form the optic radiation), but also to higher visual cortical areas and to subcortical areas such as the superior colliculus (SC). The role of the extrastriate cortical pathways is still a topic of extensive investigation; from clinical cases it is evident, however, that patients with lesions to the striate cortex retain little or no useful vision. The roles of the tectal pathways, including mutual connections between cortical areas, the SC and the pulvinar, are also far from completely understood. It is thought, for example, that cortical connections with midbrain areas are essential for maintaining and shifting attention, rather than for processing detailed visual information.

5.4.3. Anatomy and Physiology: Visual Cortex

The visual cortex occupies the occipital and parts of the parietal and temporal lobes of the cerebral cortex. Like the entire cortex, it forms a highly folded structure, with a thickness of approximately 1.5 mm. It is surrounded by the cerebrospinal fluid, several layers of meninges—pia mater, arachnoid, dura, and the skull.

Like the retina, the visual cortex is a layered structure, in which different cell groups perform different tasks. Along its two-dimensional surface, one finds an orderly mapped representation of the outside world. Unlike the retina, the cortex consists of multiple areas, hierarchically organized, each of which performs a partial processing task in the analysis of the scene around us. At the present time, over 30 visual cortical areas per hemisphere are recognized in monkey, and a smaller number of more expanded areas are thought to exist in humans.

The first cortical representation, in the striate cortex, is shown schematically in Figure 5.5. It presents a straightforward map of the visual world, but contains four major transformations.

The projection from the LGN (and thus retinal ganglion cells) onto V1 input cells has approximately constant density, which means that the central visual field is highly overrepresented in the visual cortex: Roughly 20% of V1 represents the retinal fovea, and thus the central 1° – 2° of the visual field, with rapid drop-off of the density toward the periphery. This nonhomogeneous map is conveniently expressed by the cortical magnification factor, M' , i.e., the number of mm of cortex devoted to 1° of retina, as a function of eccentricity.

The folding of the human cortex, prompted by the evolutionary expansion of higher (cognitive) processing has resulted in an arrangement where most of the peripheral visual field is represented in portions of V1 that are buried in the medial walls and sulci of the cortical hemispheres. Only the foveal representation, situated along the border of V1 and the adjacent area V2, is exposed at the surface of the occipital cortex. More peripheral visual field areas are represented along the medial walls of the cerebral hemispheres, and in deep sulci embedded within these areas.

V1 has an intricate columnar structure on a scale of approximately 1 mm^2 , in which cells are arranged in inter-

secting patterns with different receptive field characteristics: One direction contains bands of cells receiving alternating projections from the two eyes, and roughly perpendicular to these ocular dominance bands, but curving into a radial “pinwheel” arrangement centered around singularities within these bands, one finds cell populations with a gradual shift in preferred stimulus orientation in superficial (2 and 3) and deep (5) cortical layers. Independently one finds cells with more straightforward properties: So-called “simple” cells in layers 4a/b/c receiving input directly from the LGN, and cytochrome oxidase (CO)-rich blobs in layers 3 and 5 in which cells show clear color specificity. The widely held notion that the striate cortex in primates contains a regular arrangement of repeating “hypercolumns” has been challenged by a more plausible arrangement in which ocular dominance and orientation specificity self-organize independently around CO-rich blobs in the course of visual development. Whichever model may be closest to reality, it is clear that the striate cortex does not provide homogeneity and isotropy, even on a local scale. Homogeneity and anisotropy may be even more pronounced in higher cortical areas (Freund, 1973).

As explained previously for ganglion cell and LGN characteristics, even the signals arriving in the cortex do not carry simple point-to-point representations of the visual field. From the complex processing network in V1 hypercolumns emerge feed-forward signals to higher cortical areas. In turn, feedback signals from these higher areas further influence local signal processing. Moreover, subcortical signals modulate the activity level in response to state changes such as sleep and arousal.

5.4.4. Anatomy and Physiology: Subcortical Pathways

While the visual pathway to the LGN and striate cortex receives the great majority of retinal ganglion cell axons, there exist subcortical pathways as well, formed by optic nerve fibers projecting to pretectal nuclei and to the pulvinar. In primates, the projections to the pregeniculate nucleus and pulvinar are thought to be of minor importance, and may be thought of as anatomical evolutionary remnants. For example, in lower mammals, ablation of striate cortex at birth allows these projections to greatly increase in density, leading to the development of crude functional vision, but similar experiments in newborn monkeys show neither the proliferation of projections nor appreciable acquisition of visual function (Cowey et al., 1994; Cowey et al., 2001).

However, other projections in primates, in particular those to the pretectal nucleus of the optic tract (NOT) and the terminal nuclei (TN) of the accessory optic system, have been demonstrated to play an important role in the rapid control of eye position through vestibulo-ocular reflex, saccades, and sustained fixation.

Detailed studies of anatomy and physiology of the primate eye movement system over the last several decades in awake, trained animal models have shown that the NOT receives information on “retinal slip,” i.e., generalized displacement of the

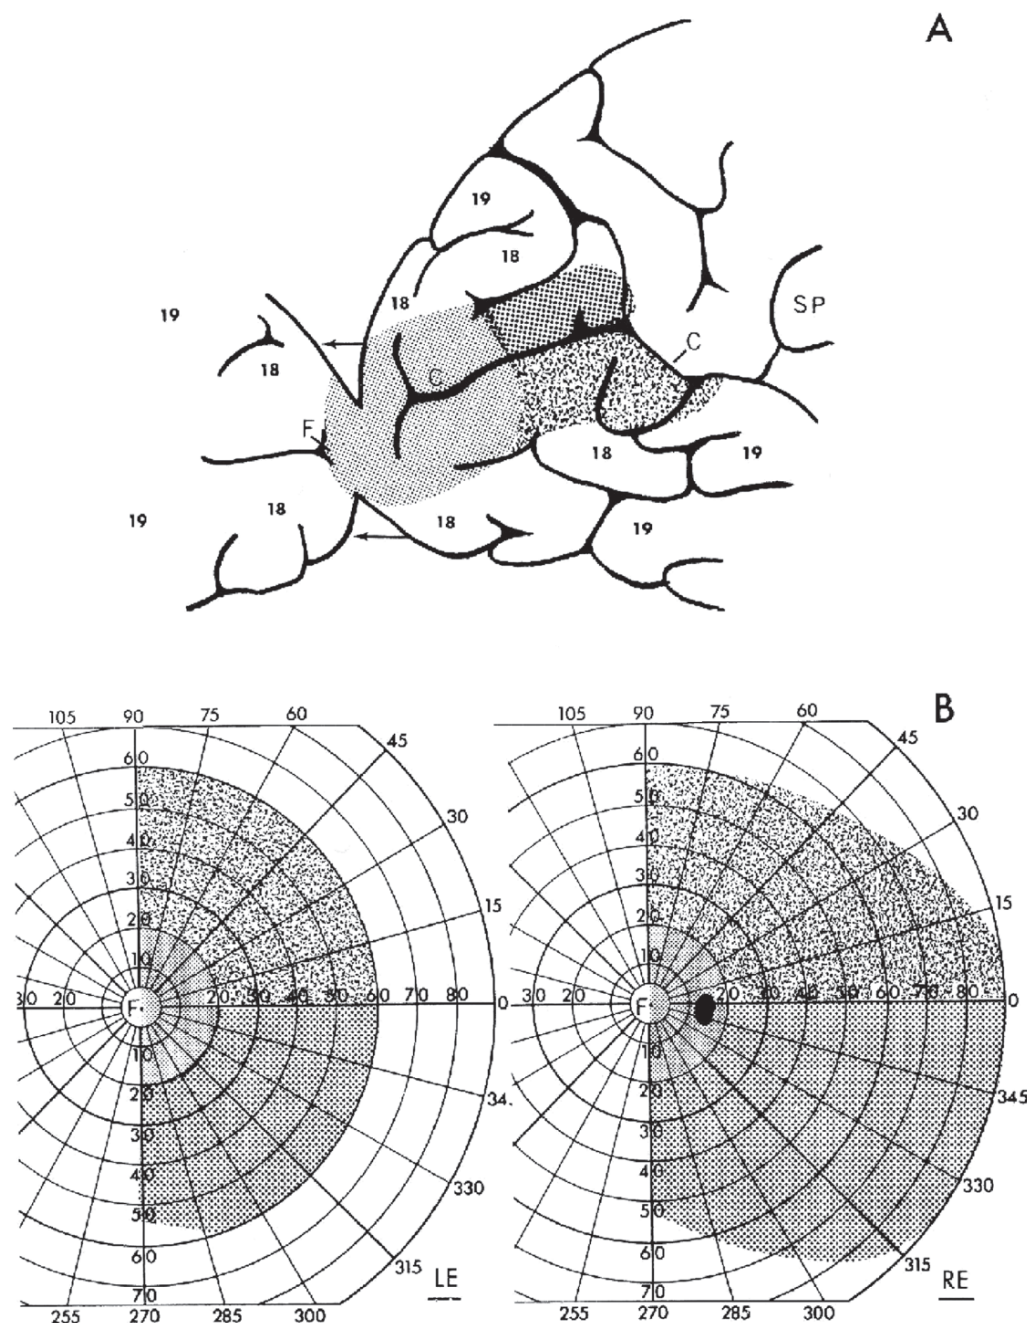

FIGURE 5.5. V1 projection of the visual field. The medial wall and part of the occipital surface of the left cerebral hemisphere (A) and the corresponding visual fields for the two eyes (B) are shown. Note that the projection of the fovea (F) and a narrow surrounding hemicircle of the visual field project onto the occipital cortex, with the projection of the vertical meridian adjacent to area V2, whereas more peripheral areas—including most of the macula—projects to the medial wall of the cortex, with much of the projection buried in the calcarine fissure (C). Also note that the left hemisphere receives information from the right visual hemifield, that the superior visual field projects to the inferior part of V1—i.e., gross localization is preserved from retina to V1, and that corresponding retinal locations in the two eyes project to the same cortical location. No such locations exist for the far nasal segment of the right retina (60° – 90°), as the bridge of the nose blocks the corresponding area in the left eye. (Illustration from “Neuroprosthetics: Theory and Practice,” Chapter 17, 2004. Used with permission from World Scientific Publishing Co.)

retinal image (Mustari and Fuchs, 1989). This retinal slip signal is encoded as a velocity signal, and serves as input to the neural integrator in the nucleus prepositus hypoglossi (Mustari and Fuchs, 1989). Pathways between the NOT and primary visual

cortex (as well as multiple similar projections between cortical and subcortical structures) are also known to exist, and have been shown to compensate in part for lesions to the NOT or its retinal input (Mustari and Fuchs, 1989; Hoffmann, 1996).

5.5. Retinal Immunology

Distinctive immunologic characteristics of the eye were well documented and led to the concept of immunologic privilege. The success of corneal transplantation established the eye as a site for tissue transplantation (von Hippel, 1888). Later, the harvesting and transplanting photoreceptors or retinal pigment epithelial (RPE) cells into subretinal space further demonstrated this characteristic (Silverman et al., 1992, Silverman and Hughes, 1989; Kaplan et al., 1997). This is influenced by the existence of immunologic privilege in the subretinal space and immunogenicity of the transplanted tissue.

As mentioned above, immune privilege in the eye is thought to be the result of a combination of anatomic features with a special molecular environment. An absence of lymphatic drainage, blood-ocular barrier, the presentation of antigen to the host via the circulation (camero-splenic axis), and the reduced expression of MHC class I and II molecules on resident cells in the AC are the anatomic features that contribute to immune privilege (Streilein et al., 1997). In a similar manner, the subretinal space is protected by a blood-ocular barrier, via tight junctions between RPE cells, as well as the vascular endothelium of the retinal circulation. The subretinal space has no lymphatic drainage and has reduced expression of MHC class I and II molecules on parenchymal cells of the neurosensory retina (Wang et al., 1987).

Some of the molecular mechanisms necessary to achieve and maintain immune privilege in the AC also exist in subretinal space.

1. Complement inhibition: There have been several complementary regulatory proteins identified immunohistologically in the eye. Their role is to protect intraocular tissue from complement-mediated destruction. There is a selective expression of CD59 (inhibiting formation of complement) in the neurosensory retina, but not membrane cofactor protein (MCP or CD 46) or decay-accelerating factor (DAF or CD55), which are expressed within the AC, and both of which participate in the regulation of complement activation (Bora et al., 1993).
2. Fas ligand-mediated apoptosis: Fas-ligand is a membrane protein that is a member of the TNF family of proteins expressed on activated T cells. Fas ligand binds to Fas, thus stimulating a signaling pathway leading to apoptotic cell death of the Fas-expressing cell. Fas ligand is expressed in various ocular tissues, including the RPE and neurosensory retina. Experiments in vivo and in vitro suggest that constitutive expression of Fas ligand in a tissue leads to a deletion of Fas+ T cells that enter the tissue (Griffith et al., 1997; Jorgenson et al., 1998).
3. Immunosuppressive molecules: Aqueous humor contains several immunomodulatory substances, including TGF- β_2 , free cortisol, IL-1 receptor antagonist, substance P and vasoactive intestinal peptide. It has been shown that RPE

secretes TGF- β_2 as well. This immunosuppressant is found in the vitreous gel of the eye.

Thus, the existence of a limited immune privilege in the subretinal space is the result of antigen-specific inhibition of cellular and humoral responses. After the introduction of an antigen into the subretinal space, a suppression of delayed-type hypersensitivity to soluble-protein antigens and a delayed rejection of allogeneic RPE cells are seen. These phenomena are the result of the inhibition of cell-mediated immunity. In the AC, delayed-type hypersensitivity is inhibited while the cytotoxic antibody response is exaggerated. In the subretinal space, both antibody production and delayed-type hypersensitivity are inhibited. This is an important difference between the immunologic privilege process within the AC and the subretinal space.

Most of the experimental studies involving placement of alloantigens in the subretinal space have been performed in rodents, and much about the nature of the immune privilege in the subretinal space remains unknown. Also, the immunogenetic disparity between donor and host is not known, so naturally, a question arises, whether immunosuppression is necessary at the time of allogeneic transplant. The survival of the allogeneic transplant is dependent on the presence of immune privilege at that site, as well as the immunogenicity of the transplanted tissue. There are studies demonstrating that RPE cells express MHC class I but not class II molecules. They can express class II molecules when stimulated with interferon- γ (Liversidge et al., 1988; Liversidge et al., 1998). The RPE also express ICAM-1, a molecule necessary for T-cell activation (Liversidge et al., 1990). The expression of MHC class II and ICAM-1 on the apical plasma membrane of cultured RPE suggests that these molecules may play an important role in the presentation of antigen to the host (Percupo et al., 1990; Osusky et al., 1997).

There are many retinal diseases for which currently no effective treatment exists. The potential usefulness of retinal transplantation as a treatment option can be explored once the knowledge of the parameters determining the immunologic rejection of allogeneic retinal transplant and biologic mechanisms of cells transplanted into subretinal space are better known.

5.5.1. Retinal Antigens and Autoimmunity

In 1968 Wacker & Lipton developed an excellent animal model of experimental autoimmune uveitis (EAU) (Wacker and Lipton, 1968). The EAU model has been used for several decades in eliciting immune mechanisms, the identification of pathogenic epitopes of autoantigens in the eye in animals, and the evaluation of therapeutic strategies.

Retinal antigens, such as S-antigen (arrestin), interphotoreceptor retinoid-binding protein (IRBP), rhodopsin, recoverin, and phosducin, appear to hold uveitogenic properties. Immunization with these antigens or their fragments can induce

ocular inflammation in susceptible strains of laboratory animals. New eye autoantigens have been discovered, such as uveal autoantigen with coiled domains and ankyrin repeats (UACA) in patients with Vogt-Koyanagi-Harada disease (Yamada et al., 2001).

EAU models using S-antigen and IRBP (peptides derived from these proteins) contributed mostly to our knowledge of retinal autoimmunity. S-antigen, a 48-kDa protein (arrestin), is one of the antigens used to induce EAU (Singh et al., 1988). It is the first retinal autoantigen that has been implicated in the pathogenesis of uveitis (Hirose et al., 1989; Merryman et al., 1991). The main action of arrestin is blocking the interaction of rhodopsin with the G-protein transducin in the phototransduction cascade. Immunization of susceptible animals with S-antigen induces a predominantly CD4+ T-cell-mediated inflammatory response in the retina, uveal tract, and the pineal gland. S-antigen has been implicated in the pathogenesis of uveitis through molecular mimicry. It has been demonstrated that several exogenous antigens, such as baker's yeast, *Escherichia coli*, hepatitis B virus, streptococcal M5 protein, Moloney murine sarcoma virus, and baboon endogenous virus, and several endogenous antigens, such as human leukocyte antigen B-derived peptide, tropomyosin antigens share sequence homology with uveitogenic peptide M of S-antigen (Shinohara et al., 1990). Antistreptococcal monoclonal antibodies were found to recognize several uveitogenic peptides of S-antigen, thus suggesting that immunological mimicry between self and exogenous antigens from an infectious agent may be a potential mechanism in the pathogenesis of uveitis in humans (Lerner et al., 1995).

IRBP is a major protein (1264 amino acid residues) of the interphotoreceptor matrix. It functions as a transporter of retinoids between the retina and RPE. It is found in both the eye and the pineal gland. A spectrum of disease ranging from hyperacute to chronic relapsing disease could be induced with variable doses of this antigen. The inflammation is located at the photoreceptor layer, producing histopathology similar to that seen in uveitis, retinal vasculitis, granuloma, focal serous detachments, loss of photoreceptors, and formation of sub-RPE infiltrates resembling to Dalen-Fuchs nodules (Caspi et al., 1988). The relatively long duration of disease activity in the murine IRBP EAU model makes it a good model for evaluation of therapeutic strategies in established disease (Chan et al., 1990).

Retinal autoimmunity is a complex mechanism that has previously been thought to be always pathological. However, based on recent studies, retinal autoimmunity now appears to have certain neuroprotective qualities. One such study showed that vaccination with peptides derived from IRBP resulted in protection of retinal ganglion cells from glutamate-induced death or death as a consequence of optic nerve injury (Mizrahi et al., 2002). It is evident that the immune system not only protects the body against invading pathogens but also protects it from toxic substances released by the body's own tissues during stress and trauma. So, the autoreactive cells that induce neuroprotection and those that induce autoimmune disease may share

the same qualities, indicating their potential to be protective and destructive at the same time (Kipnis et al., 2002). Lymphocytes reactive to retinal antigens have been found in healthy individuals (Mizrahi et al., 2002; Nussenblatt et al., 1980). The presence of circulating autoreactive cells in healthy humans suggests that immunoregulatory mechanisms are probably in place to prevent retinal autoimmunity. It appears that the ability to protect the eye from inflammation and injury does not purely depend on mechanisms of immune privilege but instead on a precise regulation of autoimmunity.

Summary

The eye has been recognized as an immune-privileged site for more than 100 years. Medawar demonstrated this by showing a prolonged, often indefinite, survival of organs or tissue grafts in the anterior chamber of the eye (Medawar, 1948). Immune privilege is a dynamic process in which immunoregulatory mechanisms combined with anatomical factors maintain the vitality of grafts in privileged sites. ACAID is the best-studied immune-privilege phenomenon in the eye. Although it is an anterior-chamber phenomenon, there is enough evidence to show that there are some of the same mechanisms at work in the vitreous and subretinal space (Jiang et al., 1993). Therefore understanding ACAID could possibly further our knowledge of retinal autoimmunity.

Historically retinal autoimmunity has been considered pathogenic. So, active suppression of retinal immunity was thought to be necessary for the health of the eye. However, later studies have demonstrated the presence of retinal autoantibodies in normal controls (Yamamoto et al., 1993). Animal optic nerve injury studies suggested possible beneficial roles of retinal autoimmunity in controlling collateral damage to the retinal ganglion cells (Kipnis et al., 2002). Thus, retinal autoimmunity can be viewed as both protective and destructive phenomenon.

With the growing sophistication of molecular immunology techniques, there is more hope for elucidation of complex mechanisms of ocular inflammation.

Review Questions/Problems

1. How many compartments the eye contains?

- Three: cornea, anterior chamber and posterior chamber
- Two: anterior and posterior chamber
- Four: cornea, anterior chamber, posterior chamber and vitreous cavity
- Three: anterior chamber, posterior chamber and vitreous cavity

2. What is the volume of vitreous cavity on average?

- 2 mL
- 4 mL

- c. 6 mL
- d. 8 mL
- e. 10 mL

3. Anterior chamber angle includes all of the following structures except:

- a. Schwalbe's line
- b. Sclera
- c. Ciliary body
- d. Lens
- e. Iris
- f. Schlemm's canal
- g. Trabecular meshwork

4. Aqueous is produced by:

- a. ciliary epithelium
- b. corneal endothelium
- c. Schlemm's canal
- d. trabecular meshwork
- e. iris roots

5. All of the following are immune privileged sites except:

- a. cornea
- b. conjunctiva
- c. lens
- d. vitreous cavity and subretinal space
- e. testis and ovary

6. Which statement is not true regarding immune privilege?

- a. The phenomenon of immune privilege was initially described in the nineteenth century.
- b. Immune privilege is defined as a prolonged, sometimes indefinite, survival of organ or tissue grafts at special body/organ sites.
- c. Immune privilege is a dynamic process maintained by anatomic structures and immunoregulatory forces.
- d. Grafts placed in immune privileged sites remain sequestered from the immune environment.
- e. Both active and passive factors of immune privileged sites and tissues contribute to the privileged status.

7. All the following is true about anterior chamber immune associated deviation (ACAID) except:

- a. ACAID is an antigen-specific systemic immune response to eye-derived antigens.
- b. ACAID is an actively acquired and actively maintained manifestation of ocular immune privilege.
- c. In ACAID aqueous humor possesses immunomodulatory properties and inhibits all immune reactions.
- d. ACAID is a form of peripheral tolerance, unlike central tolerance, where clonal deletion and/or anergy occur within the thymus.
- e. Once induced, ACAID persists for a very long period of time.

8. Visual cortex occupies the following structures:

- a. occipital and parts of the parietal and temporal lobes of the cerebral cortex
- b. parietal and parts of occipital and temporal lobes of the cerebral cortex
- c. lateral geniculate body, occipital and frontal lobes of the cerebral cortex
- d. frontal and parts of occipital and temporal lobes of the cerebral cortex
- e. occipital and parts of frontal and parietal lobes of the cerebral cortex

9. Which substance found in the eye is not uveitogenic?

- a. S-antigen (arrestin)
- b. TGF- β
- c. interphotoreceptor retinoid-binding protein (IRBP)
- d. recoverin
- e. phosducin

10. Which molecules do not possess immunosuppressive properties?

- a. free cortisol
- b. IL-1 receptor antagonist
- c. substance P
- d. rhodopsin
- e. vasoactive intestinal peptide

6.1. Introduction

The hippocampus is a brain structure located inside the temporal lobe. It forms a part of the limbic system and plays an important role in the formation, consolidation and retrieval of episodic memories. It has been shown that repetitive activation of excitatory synapses in the hippocampus causes an increase in synaptic strength that last for hours or days designated as long-term potentiation (LTP). It is widely believed that LTP provides an important key to understand the cellular and molecular mechanisms by which memories are formed and stored. Sensory information enters the hippocampus mainly through the perforant pathway consisting of the axons of neurons in layer II and III of the entorhinal cortex. The perforant path axons terminate on the dendrites of the dentate gyrus granular cells. Then information flows through the hippocampus from the dentate gyrus to the CA3, the CA1 and the subiculum, forming hippocampal intrinsic trisynaptic circuit. In addition to its “traditional” role in learning and memory, the hippocampus is also involved in neuroimmunity. Lesion of hippocampus alters immunity and neuronal functions in the hippocampus are modulated by a variety of immune active molecules.

6.2. Anatomy of the Hippocampus

The hippocampus, so named because its shape vaguely resembles that of a seahorse, is a symmetrical structure located inside the medial temporal lobe on both sides of the human brain. It is a curved sheet of cortex folded into the medial surface of the temporal lobe. In transverse sections from rodent brain, the hippocampus has the appearance of two interlocking Cs with three distinct sub-fields, the dentate gyrus, the hippocampus proper (cornu

ammonis, CA) and the subiculum. Although there is a lack of consensus to terms describing the hippocampus and the adjacent cortex, the term hippocampal formation generally applies to the dentate gyrus, fields CA1—CA3 (and CA4 is frequently called the hilus and considered part of the dentate gyrus) and the subiculum. The CA1-CA3 fields make up the hippocampus proper.

In animals, the hippocampus is among the phylogenetically oldest parts of the brain. It occupies most of the ventroposterior and ventrolateral walls of the cerebral cortex in rodents. However, the hippocampus occupies less of the telencephalon in proportion to cerebral cortex in primates, especially in humans. The significant development of hippocampus volume in primates correlates with overall increase of brain mass and neocortical development.

The anatomy of the hippocampus has been studied intensively in rodents since Cajal (1911) published his famous drawing illustrating the main cells, connections and flow of impulse traffic in the hippocampal formation (Figure 6.1). Subsequent studies using physiological, biochemical and axonal tracing techniques have added details in the cytoarchitecture and connections of the hippocampal formation, making it one of the most studied and best known structures in the brain (Raisman et al., 1966; Swanson and Cowan, 1975; Swanson et al., 1981; Frotscher, 1985).

One striking feature of hippocampal circuitry is the pattern of afferent termination. Major hippocampal afferents originating from entorhinal cortex and ipsilateral and contralateral hippocampal subfields synapse on the dendrites of the principal cells in a laminated pattern. For instance, hippocampal commissural and associational fibers synapse within the proximal one-third of the granule cell dendritic field, which is close to the cell body layer. The massive perforant path fibers terminate topographically in the outer two-thirds of the dendritic field. Afferents also have a laminar organization in the hippocampal proper.

Another important feature of the hippocampus is its intrinsic circuitry. Information flows through the hippocampus proceeds from dentate gyrus to CA3 to CA1 to the subiculum, forming the principal intrinsic trisynaptic circuit (Figure 6.1). CA2 represents only a very small portion of the hippocampus and its presence is often ignored in accounts of hippocampal function, though it is notable that this small region seems

unusually resistant to conditions that usually cause large amounts of cellular damage, such as epilepsy.

6.2.1. Dentate Gyrus

6.2.1.1. Cytoarchitecture

The dentate gyrus is a sharply folded trilayered cortex that forms a cap over the free edge of Ammon's horn (C or V shape in rodents). Its cell layer, the granule layer, contains densely packed granule cells, which are the principal neurons in the dentate gyrus. These granule cells have small (about 10 μm in diameter), spherical cell bodies, which are stacked approximately 4–10 cells thick in the granule layer. The molecular layer contains the dendrites of the granule cells, which typically show a conically shaped dendrite field. Because the dendrites emerge only from the top or apical portion of the cell body, granule cells are considered to be monopolar neurons. The granule cell dendrites extend perpendicularly to the granule cell layer, into the overlying molecular layer where they receive synaptic connections from several sources. The axons of granule cells are called mossy fibers because of the peculiar appearance of their synaptic terminals. They originate from the basal portion of the cell body and extend into the polymorphic cell layer in the hilus, a transition area between the dentate gyrus and hippocampus proper. The mossy fibers synapse onto some of the neurons in hilar area, such as mossy cells in the polymorphic cell layer. However, most mossy fibers project to the stratum lucidum of the CA3 region where

they terminate onto proximal apical dendrites of the pyramidal CA3 cells. In the dentate gyrus, the most prominent class of interneurons is called the pyramidal basket cell, of which there are at least five types. The cell bodies of these neurons are typically located at the border between the granule cell layer and the polymorphic cell layer, and their axons innervate the cell body of the granule cells. There are also interneurons in the molecular layer, the most interesting of which is an axo-axonic cell that terminates on the initial axon segments of the granule cells. Excitatory interneurons, the mossy cells, can also be found in the molecular layer. Their axons only project to the molecular layer of the ipsilateral and contralateral side.

Interestingly, the dentate gyrus is one of the few brain regions where neurogenesis takes place. Neurogenesis is thought to play a role in the formation of new memories. It has also been found to be increased in response to both antidepressants and physical exercise, implying that neurogenesis may improve symptoms of depression.

6.2.1.2. Fiberarchitecture

6.2.1.2.1. Afferents to the Dentate Gyrus—The Perforant Path

As emphasized by Cajal (1911) and later corroborated by Lorente de No (1934), the main input to the dentate gyrus is from the entorhinal cortex (but also perirhinal cortex, among others) by way of a fiber system called the perforant path. It is the major input to the hippocampus. The axons of the perforant path arise principally in layers II and III of the entorhinal cortex, with minor contributions from the deeper layers IV and V. Axons

from layers II/IV project to the granule cells of the dentate gyrus and pyramidal cells of the CA3 region, while those from layers III/V project to the pyramidal cells of the CA1 and the subiculum. The perforant fibers are laminated afferents to the dentate molecular layer and terminate in the outer two thirds of the dentate molecular layer. Thus, the perforant path represents a massive input to the dentate gyrus.

Perforant path input from the entorhinal cortex layer II enters the dentate gyrus and is relayed to region CA3. Region CA3 combines this input with signals from the entorhinal cortex layer II, makes extensive connections within the region, and sends connections to region CA1 through a set of fibers called the Schaffer collaterals. Region CA1 receives input from region CA3 and the entorhinal cortex layer III, then projects to the subiculum in addition to sending information along the output paths of the hippocampus.

The perforant path is composed of the medial perforant path and the lateral perforant path generated respectively at the medial and lateral portions of the entorhinal cortex. It was in the perforant pathway that long-term potentiation (LTP) was first discovered (Bliss and Gardner-Medwin, 1973). The medial perforant path synapses onto the inner one-third dendritic area of the granule cells, while the lateral perforant path does it onto the outer two-thirds dendrites of these same cells. Approximately 60–70% of the total dendritic fields of individual granule cells are taken up with the perforant input (Desmond and Levy, 1982). Other afferents to the dentate gyrus originate from brain stem raphe nuclei (Moore and Halaris, 1975), the locus ceruleus (Room et al., 1981) and hypothalamic supramammillary nucleus (Wyss et al., 1979).

6.2.1.2.2. Efferents from the Dentate Gyrus—The Mossy Fibers

The dentate gyrus does not project to other brain regions. Within the hippocampal formation, it only projects to CA3 via the mossy fibers (Figure 6.2). The mossy fibers are the axons of dentate gyrus granule cells. They extend from the dentate gyrus to CA3 pyramidal cells, forming their major output. Mossy fiber synapses on CA3 neurons display distinctive terminal boutons, with multiple transmitter release sites and post-synaptic densities. The mossy fiber terminals are large (3–6 μm) and make asymmetric synaptic contact on the dendritic shaft and dendritic spines (thorny excrescences) of CA3 pyramidal cells. Multiple granule cells can synapse onto a single CA3 pyramidal cell. This pathway is studied extensively as a model for the functional roles of kainate receptors in synaptic plasticity. For instance, LTP is *N*-methyl-*D*-aspartate (NMDA) receptor-independent in this pathway, but it appears to involve pre-synaptic kainate receptors. The mossy fibers are glutamatergic, however they have also been shown to be immunoreactive for GABA and opiate peptides (dynorphin and enkephalin).

There are two targets for mossy fibers: the ipsilateral CA3 fields of hippocampal proper and the mossy cells scattered

throughout the hilus. The mossy fibers descend to the hilus and ramify. Some of these collaterals branch within the hilus, while a long branch projects to CA3 area. After traveling through the hilus, the long branches group into two bundles. The infrapyramidal bundle contacts the thorny spines on proximal basal dendrites in CA3, while the suprapyramidal bundle forms the lucidum layer in CA3. Electron microscopy has revealed that varicosities in the granule cell axons contain enormous numbers of synaptic vesicles (Blackstad and Kjaerheim, 1961).

6.2.2. The Hippocampus Proper (CA1-CA3 Fields)

6.2.2.1. Cytoarchitecture

Hippocampus proper is a U-shaped fold of cortex composed of CA1—CA3 fields (Figure 6.1). The narrow layer of pyramidal neurons extends from subiculum to the hilus of the dentate gyrus. Adjacent to the subiculum is a field of tightly packed medium-sized cells, which Lorente de No (1934) named the CA1. Next to CA1 are fields CA2 and CA3 containing large, less densely packed cells. CA2 pyramidal cells can be distinguished from CA3 pyramidal cells in Golgi preparations by the absence of characteristic thorny spines on the proximal apical dendrites, but not by Nissl-staining.

In Golgi preparations, the pyramidal cells in hippocampal proper are characterized by two groups of dendrites, the apical dendrite and the basal dendrites. The apical dendrite is a single pole extending from the pyramidal apex through the stratum radiatum into the molecular layer, giving off a few branches in the CA1 field of the stratum radiatum. In the molecular layer many secondary and tertiary branches of the main dendrite produce a dense tuft. The basal dendrites originate from the base of pyramidal cells and branch in the dendritic layer between the pyramidal cell layer and the white matter surrounding the hippocampus, forming another dense tuft. The axon originates from the proximal segment of basal dendrite and travels to the alveus where it may bifurcate, especially in the CA1 field. The bifurcated axons in the CA1 field travel with one branch toward the subicular area and with the other toward the fimbria. Within the oriens layer, the axons of the CA3 pyramidal neurons give off recurrent branches, constituting the Schaffer collaterals. The Schaffer collaterals make synaptic connection to the CA1 neurons.

6.2.2.2. Fiberarchitecture

The CA3 pyramidal cells give rise to highly collateralized axons, which project both to within the hippocampus (CA3, CA2 and CA1) and also to the same fields in the contralateral hippocampus via the commissural fibers. Some of the CA3 axons project to the lateral septal nucleus. All of the CA3 and CA2 pyramidal cells give rise to highly divergent projections to all subfields of the hippocampus. The main afferents to the CA1 pyramidal cells come from the Schaffer collateral/

commissural pathway. This pathway is derived from axons that project from the CA3 region of the hippocampus to the CA1 region. The axons either come from CA3 neurons in the same hippocampus (ipsilateral) or from an equivalent structure in the opposite hemisphere (contralateral). These latter fibers are termed commissural fibers, as they cross from one hemisphere of the brain to the other. While Schaffer collaterals are often illustrated as extending only through the stratum radiatum, it should be emphasized that both the stratum radiatum and the stratum oriens of CA1 are heavily innervated by CA3 axons. This pathway is extensively utilized in the study of NMDA receptor-dependent LTP and LTD.

Unlike the CA3 field, pyramidal cells in CA1 do not give rise to a major set of collaterals that distribute within CA1, i.e. they have few associational connections. The axon can give rise to collaterals that terminate on basal dendrites of other CA1 cells. While the axon can give rise to collaterals that terminate on basal dendrites of other CA1 cells, it is clear the massive associational network that is so apparent in the CA3 is largely missing in the CA1. The CA1 also receives a fairly substantial input from the amygdaloid complex and is the first hippocampal field that originates a return projection to the entorhinal cortex. As with the CA3, however, the CA1 field receives light noradrenergic and serotonergic projections.

The septal nucleus is the major extrahippocampal target for the pyramidal cells from all CA fields. Axons from both CA1 and CA3 terminate in the septal nucleus. The fibers from dorsal hippocampal project to dorsomedial areas of the lateral septal nucleus, while progressively more ventral parts of the hippocampus terminate in correspondingly more lateroventral bands in the lateral septal nucleus (Meibach and Siegel, 1977b). Some branches of the CA1 axons terminate sparsely in olfactory bulb (de Olmos et al., 1978) and prefrontal cortex (Swanson, 1981).

6.2.3. The Subicular Complex

The subiculum curves anteriorly and laterally to wrap around the posterior extension of the dentate gyrus. It borders the medial entorhinal cortex and field of CA1 (Figure 6.1). The subiculum can be divided into three distinct cytoarchitectural areas. The parasubiculum borders the medial entorhinal cortex and contains moderately packed medium-sized cells. Next to the parasubiculum is presubiculum, which is characterized by a superficial lamina of densely packed small cells. The subiculum proper is the third distinct area. It borders anterolaterally to the field of CA1 and has a loosely packed pyramidal cell layer and a wide molecular layer.

Hippocampal intrinsic afferents to the subiculum originate from other hippocampal regions. The CA1 neurons send a dense projection to the subiculum and the CA3 pyramidal cells project to all parts of the subicular complex through the Schaffer collateral pathway (Swanson et al., 1978). The extra-hippocampal projections to the subiculum mainly originate from the raphe nuclei (Conrad et al., 1974), locus coeruleus

(Jones and Moore, 1977; Haring and Davis, 1985), amygdaloid nuclei (Krettek and Price, 1977), septal nucleus (Meibach and Siegel, 1977a) and perirhinal cortex (Kosel et al., 1983).

The subiculum is an important area for hippocampal efferents. The brain target regions for subicular projections include, but are not limited to, thalamic nuclei (Aggleton et al., 2005), reunions nucleus (Herkenham, 1978), mammillary body of the hypothalamus (Aggleton et al., 2005) and amygdala (Kishi et al., 2006). The para-subiculum and pre-subiculum project heavily to the anterior thalamic nuclei (Sikes et al., 1977; Cohen and Eichenbaum, 1993).

6.3. Role of the Hippocampus in Learning and Memory

6.3.1. Memory Functions of the Hippocampus

The role of the hippocampus in learning and memory has been the focus of neuroscience studies since Scoville and Milner reported the case of HM who had severe anterograde amnesia following bilateral medial temporal lobe resection (Scoville and Milner, 1957). The pattern of impaired and spared memory functions displayed by HM prompted a now commonly acknowledged characterization of the temporal lobe amnesic syndrome. It is widely believed that damage to the hippocampus disrupts declarative memory processes and more specifically episodic memory functions (Tulving and Markowitsch, 1998; Tulving, 2001). Declarative memories have been further divided into episodic and semantic memories. Episodic memory is concerned with conscious recall of specific episodes, and semantic memory with the storage of factual information. The memory functions that are spared in temporal lobe lesions have been classified as nondeclarative or procedural memories (Squire, 1992; Cohen and Eichenbaum, 1993). Nondeclarative or procedural memory processes are thought to operate automatically and do not include information about where or when learning experience took place. The pattern of memory deficits in humans with temporal lobe damage prompted the question, what role did the hippocampus play in memory?

The precise role of the hippocampus in learning memory remains to be determined. Accumulating evidence suggest that hippocampus has an essential role in the formation of new memories about experienced events. Damage to the hippocampus usually results in profound difficulties in forming new memories (anterograde amnesia), and normally also affects access to memories prior to the damage (retrograde amnesia). Although the retrograde effect normally extends some years prior to the brain damage, in some cases older memories remain. This sparing of older memories leads to the idea that consolidation over time involves the transfer of memories out of the hippocampus to other parts of the brain. However, it is difficult to test the sparing of older memories experimentally. Also, in some cases of retrograde amne-

sia, the sparing appears to affect memories formed decades before the damage to the hippocampus occurred, so its role in maintaining these older memories remains controversial.

Animal studies indicate that the hippocampus plays a role in storing and processing spatial information. In rodents, the firing rate of hippocampal neurons was found to correlate to the location of the animal in a test environment and these cells are referred to as place cells (O'Keefe and Dostrovsky, 1971; O'Keefe and Conway, 1978). There are many thousands of different place cells, which can be activated in response to a location in a particular environment. Different place cells have different place fields, which are not fixed in absolute space and are relative to spatial cues. The discovery of place cells led to the idea that the hippocampus might act as a cognitive map — a neural representation of the layout of the environment (O'Keefe and Nadel, 1978). There has been considerable support for the cognitive mapping theory from lesion and unit recording studies. It has been reported that rats with hippocampal lesions exhibit impairment in learning as detected in radial arm (Jarrard, 1983), T-maze (Bannerman et al., 2001) and Morris water maze, where lesioned rats had poor performance in finding the hidden platform (Morris et al., 1982; Morris et al., 1986). Indeed, neuroimaging studies in humans revealed that the hippocampus becomes active during spatial navigation, suggesting that the hippocampus in humans contributes to the encoding and retrieval of spatial information. This finding corresponds well with the results in animal studies, which show a significant deficit in spatial navigation resulting from hippocampal damage.

6.3.2. Synaptic Mechanisms of Memory

The nature of the physiological basis of learning and memory remains an enigma in neurobiology. The assumption that information is stored in the brain as changes in synaptic efficacy was initially proposed by Ramon y Cajal and later refined by Hebb (1949). This assumption was not tested until the early 1970s when Timothy Bliss and Terje Lømo made an important discovery that brief high frequency electrical stimulation of an excitatory pathway to the hippocampus produced a long-lasting enhancement in the strength of the stimulated synapses. This effect is now known as long-term potentiation (LTP).

LTP is expressed as a persistent increase in the size of the evoked synaptic response recorded from single cells or group of cells. It can be induced by high frequency stimulation (HFS, typically 100Hz) or other types of stimulation, such as theta-burst stimulation. These stimulus paradigms resemble the synchronized firing patterns and frequencies that occur in the hippocampus during learning (Otto et al., 1991), making them useful experimental means to generate “learning activities” in the hippocampus. Over the past 30 years, LTP has been intensively studied because it is the leading experimental model for the synaptic changes that may underlie learning and memory.

6.3.2.1. Basic Properties of LTP

Although LTP was first demonstrated at the perforant path synapses on the granule cells in the dentate gyrus (Bliss and Gardner-Medwin, 1973), the majority of experiments on understanding the mechanisms of LTP have been performed on the Schaffer collateral/commissural synapses on the CA1 pyramidal cells in the hippocampus.

LTP in the hippocampus has three basic properties: cooperativity, associativity and input-specificity (Bliss and Collingridge, 1993). Cooperativity refers to the fact that long-lasting synaptic enhancement following HFS increases with the number of stimulated afferents (McNaughton et al., 1978). Threshold stimulus intensity during HFS is required for synaptic enhancement. ‘Weak’ HFS, which activates relatively few fibers, does not produce LTP, whereas strong stimulation at the same frequency and for the same duration produces LTP. Associativity means that a weak input (small number of stimulated afferents) can be potentiated if it is active at the same time as a strong tetanus (large number of stimulated afferents) is applied to a separate but convergent input (Bliss and Collingridge, 1993). This associativity has often been viewed as a cellular analog of associative or classic conditioning (Malenka and Nicoll, 1999). Another basic property of LTP is its input-specificity. When LTP is induced by repetitive stimulation the increase in synaptic strength usually does not occur in other synapses (on the same cell) that are not active at the time of repetitive stimulation (Bliss and Collingridge, 1993). This property increases the storage capacity of individual neurons (Malenka and Nicoll, 1999).

One remarkable feature of LTP is that it can be induced by a brief HFS, lasting less than or equal to a second and consisting of stimulation frequencies well within the range of normal axon discharging. Longevity is an additional feature of LTP. Once induced, LTP can persist for many hours in brain slices *in vitro* or in an anaesthetized animal, and for days or weeks (possibly even a lifetime) in a freely moving animal.

6.3.2.2. Mechanisms of Hippocampal LTP

It is well accepted that activation of postsynaptic NMDA receptors, a subtype of glutamate receptors, is required for the induction of LTP in the hippocampus. The key role that the NMDA receptors play in LTP induction relies on the voltage-dependent block of its channel by Mg^{2+} (Ascher and Nowak, 1988). In this way the NMDA receptor channel complex behaves as a molecular detector for LTP induction. To trigger the induction of LTP, two events must occur simultaneously: the cell membrane must be sufficiently depolarized to expel Mg^{2+} from NMDA channels at the same time L-glutamate binds to NMDA receptors and promotes the opening of these receptor-ligand-gated ion channels. The membrane depolarization can be achieved by repetitive tetanic stimulation of synapses or by directly depolarizing the cell while continuing low frequency stimulation of synapses (Gustafsson et al.,

1987). At Schaffer collateral—CA1 pyramidal cell synapses, Na^+ ions passing through the AMPA receptors are responsible for this membrane depolarization. When the membrane depolarization is sufficient and reaches a certain level, it expels Mg^{2+} from the NMDA receptor channel, allowing Ca^{2+} as well as Na^+ to enter the cell. The influx of Ca^{2+} through NMDA receptor channel raises intracellular Ca^{2+} and triggers the induction of LTP.

Considerable evidence now links this rise in postsynaptic Ca^{2+} concentration to the induction of LTP. The most compelling evidence in support of this model comes from experimental results wherein LTP induction can be blocked by pharmacological inhibition of NMDA receptors (Collingridge et al., 1983), or prevented by the injection of a Ca^{2+} chelator into the postsynaptic neuron (Lynch et al., 1983; Yang et al., 1999). Ca^{2+} imaging studies have demonstrated that tetanic stimulation directly increases Ca^{2+} within dendrites and spines as a result of NMDA receptor activation (Regehr and Tank, 1990; Perkel et al., 1993; Yuste and Denk, 1995). Although NMDA receptors are the primary source of Ca^{2+} entry into the dendrites and spines, activation of dendritic voltage-gated Ca^{2+} channels and Ca^{2+} release from intracellular stores also elevate Ca^{2+} levels and contribute to the induction of LTP. However, the mechanisms underlying the Ca^{2+} channel-dependent LTP may differ from NMDA receptor-dependent LTP (Malenka and Nicoll, 1999).

6.3.2.3. *Expression of LTP*

It has long been a challenge for neurobiologists to identify whether the increase in synaptic strength is mediated primarily through a pre- or post-synaptic mechanism. Available experimental results indicate that the increase in the synaptic strength could be either pre- or post-synaptic or both, or through an extrasynaptic mechanism, such as reduction in uptake of glutamate by glial cells resulting in an elevated concentration of glutamate at synaptic cleft. Evidence for pre-synaptic mechanisms comes from experiments measuring the overflow of radiolabeled or endogenous L-glutamate in hippocampus before and after the induction of LTP (Bliss et al., 1986). In addition, quantal analysis of synaptic transmission reveals the proportion of synaptic failures decreases after the induction of LTP (Kullmann and Siegelbaum, 1995; Malenka and Nicoll, 1999). As synaptic failures represent the failure of neurotransmitter release or silent synapses, it was concluded that the induction of LTP is the consequence of an increase in the probability of neurotransmitter release. Evidence supporting this conclusion came from the finding that the variation around the mean of EPSCs decreased during LTP (Kullmann and Siegelbaum, 1995; Malenka and Nicoll, 1999). If the probability of neurotransmitter release increases during LTP, then the quantal content will, on average, increase and the coefficient of variation will decrease, because the coefficient of variation (SD/mean) is inversely proportional to the quantal content (Malenka and Nicoll, 1999).

Experimental results from other studies have shown a post-synaptic mechanism for LTP induction. First, paired-pulse facilitation (PPF) is not altered after the induction of LTP and this has been interpreted as evidence for a post-synaptic facilitation of LTP. PPF occurs when two pre-synaptic stimuli are delivered with a short interval (50–200 ms) and is thought to result from residual Ca^{2+} in the pre-synaptic terminal following the first stimulus, enhancing release during the second stimulus (Manabe et al., 1993). Various manipulations known to increase transmitter release do cause a decrease in the facilitation ratio, because release is already enhanced to near saturation during the first stimulus (Manabe et al., 1993). The failure in the alteration of PPF ratio suggests a post-synaptic locus of LTP expression.

A number of studies have shown that during LTP the AMPA receptor component of the EPSC is selectively enhanced, with little or no change in the component of NMDA receptors (Larkman and Jack, 1995), though both receptors are frequently co-localized at individual synapses. Pharmacological modulation of transmitter release affects AMPA and NMDA components equally, arguing for a selective postsynaptic alteration in either the density or properties of AMPA receptors (Kullmann and Siegelbaum, 1995).

6.4. Neuroimmunomodulation via Hippocampus

One of the important recent advances in understanding the biological basis of neurodegenerative disorders is the recognition that there is extensive communication between the central nervous system (CNS) and the immune system. Initial evidence that the immune system may communicate with the CNS was provided by Besedovsky et al. (1977), who observed that activation of the immune system was accompanied by changes in hypothalamic, autonomic and endocrine processes. The existence of neural-immune interactions is now supported by abundant evidence showing that the immune system communicates with the CNS through immunotransmitters (primarily cytokines) leading to direct CNS activation (Berkenbosch et al., 1987; Sapolsky et al., 1987) or by release of CNS-derived cytokines, and that the CNS regulates the immune system via neurotransmitters, hormones and neuropeptides. It has been shown that cells of immune system can synthesize and release several immunomodulatory hormones, neuropeptides and catecholamines (Blalock, 1989, 1994). For example, lymphocytes and macrophages produce the endogenous opioid peptides, norepinephrine, and epinephrine (Lolait et al., 1984; Harbour et al., 1987; Engler et al., 2005). A recent study (Rivest, 2003) shows that the CNS responds to systemic bacterial infection with innate immune reaction without pathogen's direct access to the brain. Whether caused by a microbe, trauma, toxic metabolite, autoimmunity, or as part of a broader degenerative process, activation of the immune system results in changes in the activity of discrete populations of brain neurons, including

hippocampal neurons. Accumulating evidence indicates that these mechanisms are relevant for the course of infectious, inflammatory, autoimmune and neoplastic diseases.

6.4.1. Lesion of Hippocampus Affects Immunity

It has been shown that during immune challenge the hippocampus exhibits time-dependent changes in neurotransmitter levels and that an intact hippocampus is essential for the normal humoral immunity for the primary immune response in rats (Devi et al., 2004). Lesions of the dorsal hippocampus were found to produce a transient increase in splenocytes and thymocytes, as well as increased T-cell mitogen responses (Brooks et al., 1982). Lesions of the hippocampus were also found to cause differential effects on humoral immunity depending on the lesions of different subfields of the hippocampus (Pan and Long, 1993). Axotomy of afferent fibers within the molecular layer of the dentate gyrus caused activation of neural-immune elements in the slice cultures (Coltman and Ide, 1996). In addition, electrical stimulation of hippocampus increased the number of neutrophils and phagocytic index while also decreasing the number of lymphocytes and plasma corticosterone level in rats (Devi et al., 1993). Lesions in hippocampus induced by kainic acid resulted in elevated antibody production including IgM and IgG (Nance et al., 1987). Taken together, these studies show that lesions (or stimulation) in the hippocampus affect immune functions.

6.4.2. Immunomodulation of Neuronal Functions in Hippocampus

Hippocampal neuronal activities have been examined thoroughly in studies on neuroendocrine, autonomic and cognitive function, as well as psychomotor behavior. Circumstantial evidence indicates that hippocampal physiology can be modulated by the immune system (Jankowsky and Patterson, 1999; Jankowsky et al., 2000). This modulation could be achieved through proinflammatory cytokines including, but not limited to, interleukin-1 β (IL-1 β), IL-2, IL-6, tumor necrosis factor alpha (TNF- α) and interferon gamma (INF- γ) (Wrona, 2006). Indeed, a number of cytokines, including the aforementioned ones, are expressed in the hippocampus and alteration of their expression levels can affect hippocampal functions. Studies have shown that inflammatory cytokines, released in response to the detection of foreign substances (antigens), influence ion channel activities, intracellular Ca²⁺ homeostasis, membrane potentials, and suppress or enhance the induction of LTP in the hippocampus (Koller et al., 1997). Extensive experimental results have implicated IL-1 as the most likely candidate for key immunotransmitter, communicating immunological activation to the brain including the hippocampus (Besedovsky et al., 1975; Besedovsky et al., 1986). It is worth to point out that cytokines rarely work in isolation. For instance, the release of IL-1 β is usually associated with the release of the other proinflammatory cytokines,

such as TNF- α and IL-6, which are indeed expressed in the hippocampus.

IL-1 β and its receptors are expressed in the hippocampus (Farrar et al., 1987; Ban et al., 1991; Cunningham and De Souza, 1993). High density of binding sites for IL-1 β has been detected in the hippocampus, with highest density in the dentate gyrus (Takao et al., 1990). It has been shown that peripheral immune activation by lipopolysaccharide (LPS) up-regulates IL-1 β mRNA expression and increases IL-1 β protein in the hippocampus (Laye et al., 1994; Nguyen et al., 1998). This suggests that immune activation may modulate hippocampal function via release of immune active molecules, such as IL-1 β . As hippocampus is a brain region involved in learning and memory, the immune associated upregulation of IL-1 β mRNA and protein expression may interrupt hippocampal functions such as learning and memory. Indeed, IL-1 β suppresses the induction of LTP in the CA1 and CA3 areas of the hippocampus as well as in the dentate gyrus (Katsuki et al., 1990; Bellinger et al., 1993; Cunningham et al., 1996; O'Connor and Coogan, 1999; Xiong et al., 2000), while having no significant effects on excitatory postsynaptic potential (EPSP) evoked by low frequency stimulation. The IL-1 β -mediated suppression of LTP is antagonized by an IL-1 β receptor antagonist, suggesting that IL-1 β inhibits LTP through IL-1 β receptors. In addition to IL-1, IL-2 had similar effects on LTP in hippocampus. Application of recombinant IL-2 inhibited the induction of both short-term potentiation (STP) and LTP. It also inhibited post-tetanic potentiation (PTP) and LTP maintenance without affecting basal synaptic transmission (Tancredi et al., 1990). Moreover, IL-2 deficiency results in altered hippocampal cytoarchitecture (Beck et al., 2005).

LTP was also suppressed by TNF- α in both the CA1 region (Tancredi et al., 1992) and the dentate gyrus (Cunningham et al., 1996). In the CA1, the induction of LTP was inhibited by TNF- α if the tetanic stimulation was given at least 50 min after TNF- α application. In contrast to IL-1 and IL-2, TNF- α increased basal synaptic transmission in the CA1 region of the slices acutely exposed to TNF- α (Cunningham et al., 1996) but not in the dentate gyrus. The underlying mechanisms, by which TNF- α increased basal synaptic transmission, have not been determined. Brief treatment of hippocampal slices with TNF- α did not influence LTP, while long-lasting application (>50 min) of TNF- α inhibited LTP.

Summary

The hippocampus is a symmetrical structure located inside the medial temporal lobe on both sides of the human brain. In cross-sections, the hippocampus consists of two interlocking sheets of cortex with three distinct sub-regions: the dentate gyrus, the hippocampus proper (CA1—CA3) and the subiculum. The hippocampus has a highly defined laminar structure with visible layers of pyramidal cells arranged in rows. A striking feature of hippocampus is its connection circuitry.

The connections within the hippocampus generally follow this laminar format and are largely unidirectional. They form well-characterized closed loops that originate mainly in the adjacent entorhinal cortex. Thus information flow through the hippocampus proceeds from the dentate gyrus to the CA3 to the CA1 to the subiculum, forming the principal trisynaptic circuit. Together with the adjacent amygdala and entorhinal cortex, the hippocampus forms the central axis of the limbic system and plays an important role in spatial learning and awareness, navigation, episodic/event memory, and neuroimmunomodulation.

Review Questions/Problems

1. Where is the hippocampus located in the human brain?
2. What are the three subfields in the hippocampus?
3. What are the principal cells in the dentate gyrus and the CA1 field?
4. CA1 region belongs to which subfield in hippocampus?
5. The main input to the dentate gyrus originates from which part of brain and via which fiber path?
6. The medial and lateral perforant paths project to which part of the dendrite tuft of the granule cells?
7. Mossy fibers originate from which part of the hippocampus and synapse onto the neurons of which field(s)?
8. How many groups of dendrites do a CA1 neurons have and what is the name for each group? From which part of a CA1 neuron does the axon originate?
9. What is the main afferent pathway to the CA1 pyramidal cells and from where does this pathway originate?
10. Briefly describe information flow through the hippocampus
11. Damage to the hippocampus disrupts which type of memory?
12. What are the three basic properties of LTP? Define each of the three basic properties.
13. What is the key role that NMDA receptors play in LTP induction and what two simultaneously occurring events are needed for LTP induction?

Glial and Neuronal Cellular Composition, Biology, and Physiology

Kalipada Pahan

The brain has the unique ability to affect so many things from movement to emotion to cognitive abilities. It can, together with life events, transform a person into an artist, a priest, a scientist, or a teacher. To achieve any goal, all of our body systems need to collaborate with one other. It is the brain that controls and co-ordinates the activity of all in response to environmental cues and demands with the assistance of all of the nervous system. Each and every demand is detected by our senses and messages are judged by merit, which in turn, directs particular responses. Taken together, our nervous system is concerned about sensory input and motor output. Sensory nerves collect information about the body's internal and external environment and convey it to the central nervous system (CNS). Motor nerves carry instructions on what to do. Let me describe it with an example. When we feel hungry, our internal environment generates a sensory input that provides us the awareness of hunger. Then sensory input from the external environment provides us the information on how to obtain food. Consequently, motor output is generated in the external environment to get and swallow food. Then motor activity in the internal environment assists us with the food intake to the extent until we get the nod from our sensory input from the internal environment that enough food has been consumed.

This input and output business is simply dictated by a group of cells forming the basis of the supercomputing system of the brain—called neurons. This particular group of cells forces us to revere brain as an elite organ. It is the “neuron doctrine” of Professor Cajal that contributed to the basic understanding of the organization of the CNS. As nobody in this world is unable to survive alone, neurons are also not an exception from this universal rule. Therefore, there are other cells in the CNS, called glial cells (Figure 7.1). Glial cells have diverse functions that are necessary for the proper development and function of the complex nervous system. The growing number of links between glial malfunction and human disease has generated great interest in glial cell biology.

Axons are surrounded by white matter coating called myelin that consists of a layer of proteins packed between two

layers of lipids. This myelin coating enables axons to conduct impulses between the brain and other parts of the body. Myelin is synthesized by specialized cells—oligodendrocytes in the CNS and Schwann cells in the peripheral nervous system (PNS). Although the composition of CNS and PNS myelins are not same, they are assigned for the same function—to promote efficient transmission of a nerve impulse along the axon. Schwann cells have an intimate association with axons and each Schwann cell forms myelin around a single axon, and lines up along the axon to define a single internode. On the other hand, one oligodendrocyte extends several processes and can myelinate upto 1–40 axons with distinct internodes. In addition to myelination, Schwann cells are able to migrate and phagocytose debris from the PNS. However, oligodendrocytes do not have such activity.

The major cells in the CNS are astrocytes that are believed to support the entire structure of the microenvironment (Liedtke et al., 1996) together with endothelial cell lining. In addition to structural support, astrocytes have many other important functions, such as food supply, water balance, ion homeostasis, regulation of neurotransmitters, detoxification of ammonia, organizing information network, and release of neuropeptides and neurotrophins. Because neurotrophins support the growth of neurons and astrocytes are the major producer of neurotrophins in the CNS, these cells also play an important role in neurogenesis. The other important cell type is microglia, the resident macrophages in the CNS. As happens in other organs, cells in the CNS also undergo natural cell death. Then microglia keep the CNS microenvironment clean by scavenging these dead cell bodies. In addition, when immune responses are generated within the CNS or from outside the CNS, microglia, being the primary CNS immune cells, receive and pass on that response to other cells (Carson, 2002; Rock et al., 2004). Under physiological condition, the immune response usually ends up with a logical conclusion leading to the development of a better neuroimmune system. Another less characterized glial cell type is Bergmann glia that are composed of unipolar protoplasmic astrocytes in the

FIGURE 7.1. Classification of brain cells.

cerebellar cortex. These are associated with granule cells in the developing cerebellum and with Purkinje cells in the adult cerebellum.

As part of our life, we experience stress, trauma, infection, injury etc. and come in contact with various toxic substances. Although brain is separated from the rest of our body by a well-defined blood-brain barrier, brain perceives and faces each of these challenges (Figure 7.2). Therefore, after these insults, the injured brain cell usually tries to either die or survive. When an injured cell dies, the death process usually becomes associated with increased production of proinflammatory molecules, decreased production of anti-inflammatory molecules, increase in T-helper 1 (Th1) response, decreased production of growth factors, increased expression of death genes (e.g. bcl₂, X-IAP, survivin), and over-activation of tumor suppressor genes (e.g. p53). On the other hand, during the survival of an injured cell, opposite phenomena are observed (Figure 7.2). If the survival process is accompanied by a very high Th2

response, huge production of growth factors, abnormal cell growth, and mutation of tumor suppressor genes, the injured cell may like to live as a cancerous cell. Although everybody is receiving some kind of insults or injuries, everybody does not get the disease because in healthy human beings, there is a proper balance between cell death and cell survival. When this invaluable balance is lost, we see the disease (Figure 7.2). Although there are four major cell types in the CNS, under neuroinflammatory and neurodegenerative stress conditions, only neurons and oligodendroglia succumb to cell death. On the other hand, astroglia and microglia do not die but undergo activation and gliosis under the same condition. Although glial activation is not always bad, when activated glia are forced to amplify the stress response to such an extent that it goes out of control, it helps in neuroimmune and neurodegenerative pathologies (Gonzalez-Scarano and Baltuch, 1999; Eng et al., 1992; Reier, 1986).

Another aspect that also plays a vital role in unsettling the balance between physiology and pathophysiology is dose or amount of a biomolecule. Each and every biomolecule is important for our cells. However, any good thing either in excess or in less is not good any more. For example, nitric oxide (NO), an important CNS signaling molecule, exerts profound effects depending on its dose. In neuronal nitric oxide synthase (–/–) mice, when neurons do not produce much NO, male mice become very aggressive and fight with each other (Nelson et al., 1995) much like terrorists do all the time! When this molecule is present in physiological amount, neurons feel happy and relaxed due to the activation of guanylate cyclase (GC)-cyclic GMP (cGMP) pathway and proper neurotransmission (Hawkins et al., 1998). On the other hand, when NO is produced within the CNS in excess, a bitter mood prevails over this happy mood as excess NO starts a “Hurricane Katrina” damaging cellular powerhouse mito-

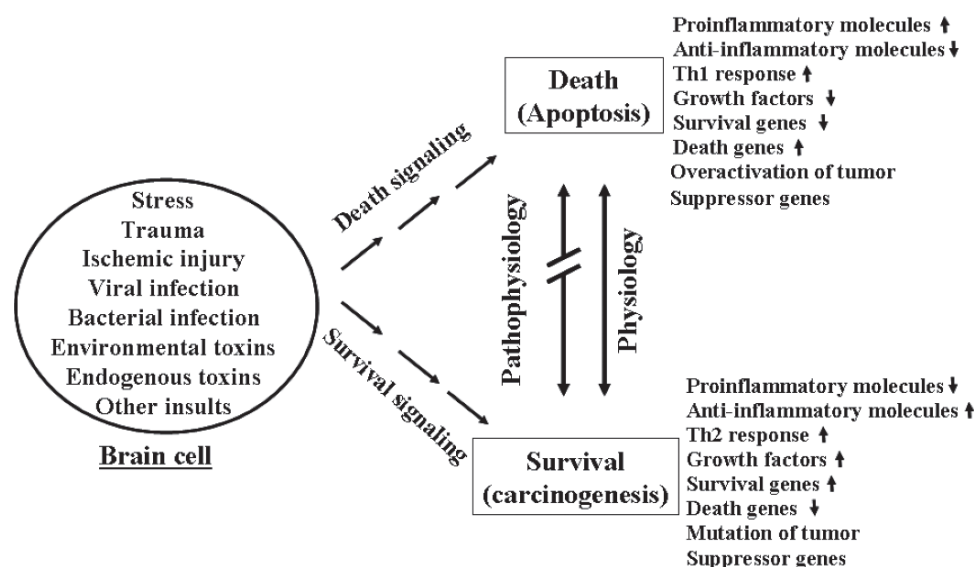

FIGURE 7.2. Balance between physiology and pathophysiology in the CNS.

chondria, inactivating essential enzymes (e.g. anti-oxidant enzymes), castrating multifunctional transcription factors (e.g. NF- κ B), oxidizing lipids, and destroying many other biomolecules (Mitrovic et al., 1994; Radi et al., 1991).

Once Sir Charles Sherrington, 1932 Nobel Laureate of Medicine, described brain as “an enchanted loom where millions of flashing shuttles weave a dissolving pattern, always a meaningful pattern though never an abiding one”. Even after more than a hundred years of research, enchanting discoveries are still coming out about this organ. We are still more or less in the dark about how to control these flashing shuttles and how to direct them to follow a certain meaningful pattern. In the following chapters, we have made an honest attempt to cover most of the known aspects of CNS physiology. A one-year old boy has about 100 billion neurons. As we grow older, neurons are lost and not replaced. However, contrary to this century-old dogma, recently it has been demonstrated that humans are able to generate new nerve cells throughout their life. Therefore, we also provide some cues for future scientists to develop the wit of transforming old and depressed minds into perpetually youthful and active minds.

Astrocytes, Oligodendrocytes, and Schwann Cells

Malabendu Jana, Subhajit Dasgupta, Anuja Ghorpade, and Kalipada Pahan

Keywords Astrocytes; Glial precursors; Calcium excitability; Astrogliosis; Oligodendrocytes; CNS myelination; Oligodendroglial death; Oligodendroglial regeneration; Schwann cells; PNS myelination

8.1. Introduction

Central nervous system (CNS) is composed of two major cell types: neuron and glia. Astrocytes and oligodendrocytes belong to the latter category. Astrocytes, through an intricate network surrounding blood vessels, play an important role in supplying food, water and ions from periphery to the CNS and maintain CNS homeostasis. Astrocytes also play an active role in neurogenesis. However, under inflammatory or neurodegenerative conditions, astrocytes produce pro-inflammatory mediators and take active part in the ongoing events. Neurons in the CNS are covered by myelin sheath that maintains conduction of nerve impulse. Consistently, the CNS houses oligodendrocytes for myelin synthesis. On the other hand, Schwann cells are the myelinating cells in the peripheral nervous system (PNS). Balanced expression of several genes and activation of transcription factors critically regulate the entire complicated functional network of astrocytes, oligodendrocytes and Schwann cells. Keeping a birds' eye view, this chapter delineates genesis and functional aspects of astrocytes, oligodendrocytes and Schwann cells.

8.2. Historical View

For decades, astrocytes and oligodendrocytes were considered as silent partners of neurons in the CNS. It was known that astrocytes, like neurons, were unable to transmit messages as they did not possess voltage and ion gated channels. With the advancement of science, it is now well accepted that astrocytes possess ion channels as well as G-protein coupled receptors necessary to sense and respond to neuronal

activities. Recent advancements also reveal that oligodendrocytes, apart from myelinating neurons in the CNS, secrete some growth factors to help neuronal growth and development. On the other hand, under disease conditions, astroglia undergo proliferation and gliosis. Activated astroglia also secrete neurotoxic molecules that may be involved in the loss of neurons in neurodegenerative disorders and the damage of oligodendroglia in neuroinflammatory demyelinating disorders.

The present chapter focuses on biology and functional aspects of astrocytes and oligodendrocytes ranging from their genesis to their enormous role in maintaining CNS homeostasis along with their role in CNS pathology. The biology and function of PNS myelinating Schwann cells has been discussed later as a separate section (Section 6).

8.3. Development of Astrocytes and Oligodendrocytes in the CNS

The vertebrate nervous system including neurons, astrocytes, oligodendrocytes, and other cells originates from a flat sheet of neuroepithelial cells, constituent of the inner lining of neural plate along the dorsal surface of embryo (Fujita, 2003). These neuroepithelial cells are the earliest precursors in the developing CNS.

8.3.1. Generation of Glial Precursor Cells

During neurogenesis, neuroblasts are first derived from stem cells and then migrate peripherally to the mantle and marginal layers in the developing brain. After that, DNA synthesis in neurons is completely ceased and the progenitor cells enter into the phase of gliogenesis in the neural tube. These glioblasts are functionally different but morphologically indistinguishable from the multipotent stem cells and eventually differentiate first into functional astrocytes and then

oligodendrocytes. The quiescent form of the glioblasts called microglia comes after these events.

Differentiation of cortical progenitor cells is being controlled by some transcription factors having basic-helix-loop-helix (bHLH) motifs. These are NeuroD, Neurogenin, Mash, Olig, Id, and Hes families of protein. The restricted and time-dependent binding of these transcription factors with corresponding DNA sequences present in the promoter of different developmental genes determines the outcome of final cell types. Recent developments (Gotz and Barde, 2005; Alvarez-Buylla et al., 2001) show that neuron and glia are generated from same progenitors/precursors.

8.3.2. Signaling Events Driving the Precursors to Functional Cells: Astrocytes and Oligodendrocytes

The signaling events like hedgehog and notch regulate genesis of functionally distinguished glia and neurons from multipotent stem cells. Hedgehog (Hh) family of signaling molecules are the key organizers of tissue patterning during embryogenesis (Altaba et al., 2002). In mouse, three Hh genes have been identified. These are Desert hedgehog (Dhh), Indian hedgehog (Ihh) and Sonic hedgehog (Shh). The Shh plays a vital role in the development of CNS. In mammals and birds, Shh is the only hedgehog family member that is reported to be expressed in normal CNS.

The oligodendrocyte progenitors (OPs) in caudal as well as ventral neural tube originate under the influence of Shh protein secreted from ventral midline. At this initial stage, Shh patterns the ventral neuroepithelium by controlling the expression of a set of transcription factors PAX6, NKX 2.2, high mobility group protein SOX10, and basic helix-loop-helix proteins Olig1 and Olig2. These Olig genes and SOX10 are co-expressed in cells before the appearance of PDGF- α on OPs. These PDGF-positive OPs then proliferate and migrate away from the ventricular surface to all parts of the CNS before differentiating into functional myelin forming mature cells.

Notch signaling (Yoon and Gaiano, 2005) first specifies glial progenitors and then functions in those cells to promote astrocytes versus oligodendrocytes fate. The ligands of the Notch signaling pathway are expressed in differentiating neurons. The receptors Notch are transmembrane proteins and are found on neural stem cells. Upon ligand binding, intracellular domain (NICD) of Notch is cleaved by γ -secretase which then enters into the nucleus to form a complex with C promoter binding factor (CBF1) and mastermind-like (MAML). Then the complex (NICD:CBF1:MAML) binds to promoter regions of target genes Hes and Herp and up-regulates corresponding HES/HERP proteins. These proteins are bHLH transcriptional regulators that antagonize proneural genes like Mash 1 and neurogenins. As a result, it blocks neuronal differentiation.

8.4. Astrocytes: Biology and Function

In the middle of the nineteenth century, German anatomist and pathologist Rudolph Virchow was wondering about the group of cells in the brain that surround the neurons and fill the spaces between them. Dr. Virchow named these cells as “neuroglia” means “neural glue.” He used the term “glue” to represent the gluing function of these cells to hold the neurons in place. Nowadays “neuroglia” is collectively used for all glial cells in the CNS. Later on, due to “star-shaped” appearance, the major neuroglial cells were named as “Astrocytes” (Astra: star; cyte: cells).

8.4.1. Morphology and Markers

Morphologically, astrocytes can be classified into two types: fibrous astrocytes and protoplasmic astrocytes (Brightman and Cheng, 1988). Fibrous astrocytes are located predominantly in white matter and possess fewer but longer processes. These processes form cytoplasmic bundles of intermediate filaments (IFs). The major constituent of these filaments are glial fibrillary acidic protein (GFAP). Under light microscope, the fibrous astrocytes look like a star-shaped cell body with finer processes. These processes are extended for long distances and contain abundant IFs.

The protoplasmic astrocytes, on the other hand, have more complex morphology. They contain highly branched processes that form membranous sheets surrounding the neuronal processes, cell bodies and end-feet on capillaries. In contrast to fibrous astrocytes, these cells have fewer IFs and a greater density of organelles.

Apart from the ultrastructural study, astrocytes can also be identified on the basis of marker proteins (Table 8.1).

8.4.2. Heterogeneous Population of Astrocytes in the CNS

In the CNS, many cells share some characteristics with astrocytes. These “astrocytes-like” cells are pituicytes, tanycytes,

TABLE 8.1. Markers of astrocytes.

Marker	Function	Cellular localization	Molecular weight
GFAP	Major constituent of intermediate filament found mostly in adult astrocytes	Cytoplasm	50 kDa (predicted)
EAAT1	Transport of amino acids	Cytoplasm	59.5 kDa
Glutamine synthase	In CNS, the enzyme found only in astrocytes; it catalyzes conversion of glutamate to glutamine	Cytoplasm	43 kDa
S-100	Ca-binding proteins	Cytoplasm/ Nucleus	21–24 kDa

GFAP, glial fibrillary acidic protein; EAAT1, excitatory amino acid transporter

ependymal cells, and Müller glia (Brightman and Cheng, 1988). “Bergmann glia” or Golgi epithelial cell, one of the astrocyte subtypes, is found mainly in cortical region of the cerebellum. The soma of such cell type is located in the Purkinje cell layer; they extend very long processes that end at the glia limitans of pia mater and large blood vessels. Also, there are astrocytes in white matter with more protoplasmic topology and with mixed fibrous and protoplasmic features.

On the basis of morphology and antigenicity, astrocytes from optic nerve cultures were designated as type 1 and type 2 (Raff et al., 1984). The type 1 astrocytes were originally defined as flat, polygonal cells that expressed GFAP but did not bind anti-ganglioside monoclonal antibodies A2B5 or R24 and LB1 except rat neural antigen 2 (Ran 2). These type 1 astrocytes proliferate well in the presence of epidermal growth factor and are found during gliogenesis in early developmental stage. On the other hand, type 2 astrocytes are found as GFAP⁺A2B5⁺ cells in rat optic nerve culture.

However, it is yet to know whether these morphologically distinct heterogeneous populations of astrocytes are also different in their function or such morphological differences are merely intrinsic.

8.4.3. Physiological Role of Astrocytes in the CNS

8.4.3.1. Maintaining CNS Homeostasis

8.4.3.1.1. Providing Structural Support

Astrocytes have long been considered as structural support cells of the brain. The anatomy of brain microvasculature shows that astrocytic end feet constitute an envelope around blood vessels (Kacem et al., 1998). Astrocytic processes are positioned beneath the pial membrane and the ependymal surface and thereby segregate the CNS parenchyma from external environment (Figure 8.1). The cytoplasmic processes of astrocytes form a close network around the synaptic complex and maintain synaptic integrity (Newman, 2003).

8.4.3.1.2. Maintaining Water Balance

Water is essential in the CNS for formation and maintenance of cerebrospinal fluid. Water enters into the CNS either through diffusion due to difference in osmotic pressure or through some specified channels. Astrocytes, through membrane-bound transporter system, maintain water and ionic homeostasis in the brain. The co-transporter system like “sodium-glutamate co-transporter” (Na⁺-glutamate, EAAT1) and sodium-potassium-chloride ion co-transporter (Na⁺-K⁺-Cl⁻ co-transporter, NKCC) are located on astroglial membrane and regulate astrocytic water transport into the CNS (Figure 8.1).

Apart from the co-transporters, astrocytic perivascular system in the brain involves membrane-bound water channels, called aquaporins (Nagelhus et al., 2004). These water channels

FIGURE 8.1. Maintenance of CNS integrity by astrocytes. Astrocytes endfeet forms a network on blood capillary and regulate transfer of water, ions and sugars. The pre-synaptic position of astrocytes is critical for the uptake of excitotoxic glutamate from neuronal synapse.

specifically mediate water fluxes within the brain. Among several members of the aquaporin family, aquaporin 4 and 9 are expressed in astrocytes. The activity of aquaporins is regulated by transmembrane G-protein coupled receptor (GPCR) family of hormonal receptors.

8.4.3.1.3. Maintaining Ion Homeostasis

Astrocytes are responsible in maintaining extracellular K⁺ ion concentration at a level compatible with neuronal function. Astrocytes form a syncytium through which it efficiently redistributes K⁺ from perineuronal to perivascular space. Such redistribution of K⁺ is mediated by inwardly rectifying K⁺ ion channels. One such K⁺ ion channel Kir 4.1 is expressed in astrocytes surrounding neuronal synapses as well as blood vessels in the brain (Nagelhus et al., 2004).

In addition to having K⁺ channels, astrocytes bear plenty of other ion channels; function of many of them is still under research. Astrocyte cell surface bears an atypical sodium channel Nax that is assumed to be under voltage-gated sodium

channel family. Nax is exclusively localized to perineuronal lamellate processes extended from ependymal cells and astrocytes. It has been suggested that glial cells bearing Nax channel are the first to sense a physiological increase in sodium level in body fluids (Watanabe et al., 2002).

8.4.3.1.4. Regulating Neurotransmitter and Amino Acid Levels

Astrocytes are active participants in the formation of tri-partite synapse and modulate synaptic activity of neurons. Glutamate plays a central role in astrocytic-neuronal interactions. This excitatory amino acid released by neurons, is taken up by astrocytes from the neuronal synapses via their glutamate transporters. Astrocytes convert glutamate into glutamine and release into the synaptic cleft for being taken up by neurons (Hertz and Zielke, 2004). Astrocytes express several receptors linked to ion channels and second messenger pathways. Activation of receptors e.g. metabotropic glutamate receptor, in turn, elevates intracellular level of Ca^{2+} . Calcium-dependent glutamate release from astrocytes modulates the activity of both excitatory and inhibitory synapses (Figure 8.1).

Apart from glutamate, astrocytes also uptake neurotransmitters like gamma amino butyric acid (GABA), aspartate, taurine, β -alanine, serotonin, and catecholamines. The fate of all these neurotransmitters is to be metabolized within astrocytes.

8.4.3.1.5. Detoxifying Ammonia

Ammonia is toxic for the CNS. Ammonia toxicity may result in neurological abnormalities leading to seizures, mental retardation, brain edema, convulsion, and coma. One of the most important enzymes that catalyze the formation of ammonia in the brain is glutamate dehydrogenase. This enzyme catalyzes reversible oxidative deamination of glutamate and produces ammonia particularly in astrocytes, thereby provides a mechanism for the removal of excess nitrogen from certain amino acids. Brain lacks carbamoyl phosphate synthase 1 and ornithine transcarbamylase, essential enzymes for the urea cycle, and thereby unable to remove accumulated ammonia (Cooper and Plum, 1987). However, astrocytes convert excess ammonia to glutamine via glutamine synthase (Figure 8.1). The excreted glutamine from astrocytes is taken up by neurons. In fact, either in physiological condition or even in hyperammonemic condition, rapid conversion of ammonia to glutamine in astrocytes is the predominant detoxification event in the CNS (Bak et al., 2006).

8.4.3.2. Supplying Energy

Glucose and ketone bodies are the primary source of energy in mammalian brain under normal physiological conditions. In comparison to its weight, which is only 2–3% of total body weight, brain consumes up to one fourth of body's total glucose supply.

8.4.3.2.1. Glycolysis

Astrocytes are the major food depot in the CNS. The food is stored in the forms of glycogen. Several studies suggest that glycogen phosphorylase and synthase are predominantly localized in astrocytes. Glucose is utilized in astrocytes mainly via glycolysis (Wiesinger et al., 1997). Deprivation of glucose in cultured astrocytes results in reduction in ATP/ADP ratio and membrane depolarization. Sugars enter into the metabolic pathway through phosphorylation which is considered as rate determining step. Astrocytes express hexokinase 1, the primary isoform of hexokinase in the CNS. This enzyme is mostly localized in mitochondria, only about 30% of it is found in cytosol.

8.4.3.2.2. Oxidative Metabolism

In order to generate energy in the form of ATP, sugars are bound to enter into oxidative metabolic pathway, the tri carboxylic acid cycle (TCA cycle) (Figure 8.1). Glycolysis generates 2 molecules of ATP and the TCA cycle generates 30 more ATP molecules from one molecule of glucose. The formation of energy in astrocytes is either through utilization of glucose under normal physiological condition or from reserve food storage glycogen via gluconeogenesis.

8.4.3.3. Organizing the Information Network in the CNS

As has been discussed earlier, astrocytes outnumber neurons by about ten to one in the CNS; and yet, historically they were considered to be a sort of glue ($\gamma\lambda\iota\alpha$) or connective tissues of the CNS. In the recent years though, it is increasingly clear that astrocytes form an integral and active component of the information network in the CNS and have received the “stardom” reflecting their morphology (Haydon, 2001; Nedergaard et al., 2003; Ransom et al., 2003). Astrocytes thus are a critical participant of “the tripartite synapse” (Araque et al., 1999; Perea and Araque, 2002). Indeed, not too long ago an entire book dedicated to “The Tripartite Synapse” that discussed in excellent detail, the anatomical and functional basis of neuroglial interactions, astrocyte calcium excitability, and the role of astrocyte in regulation of synaptic function (Volterra et al., 2002). Any discussion on astrocyte biology is thus incomplete without a consideration of their role in information transfer and intercellular communications in the brain. The details of the molecular mechanisms of this process via specific signaling events in health and disease will be discussed later in this book (see chapter by Pahan and Bidasee). This section highlights the current information on the glial communication networks of metabolite transport through gap junctions and the importance of calcium as a hallmark regulator of glial function.

8.4.3.3.1. Role of GAP Junctions

In the brain, astrocytes form a syncytium, or a network of integrated cells (Scemes, 2000). Such a syncytium consists of astrocytes that have cytoplasmic continuity in adjacent cells

through gap junctions (Bennett et al., 2003). Gap junctions serve as a conduit between two astrocytes and consist of two hemichannels, also called connexones. These hemichannels or connexones are contributed by the juxtaposed cells and together form the gap junction (Figure 8.2). Hemichannels assembled in the endoplasmic reticulum consist of junctional proteins belonging to the family of connexins (Contreras et al., 2003; Saez et al., 2003). Although a variety of connexins are expressed by astrocytes, connexin (Cx) 43 is the predominant astrocyte connexin (Theis et al., 2005). These gap junctions form channels or pores about 1–1.5 nm in diameter and permit transfer of small metabolites including, but not limited to, NAD, ATP, glutamate and Ca^{2+} (Saez et al., 2005). Gap junctions formed with Cx43 are also permeable to dyes, such as Lucifer yellow or propidium, which serve as experimental tools for studies on gap junction function. The presence of gap junctions between astrocytes and the tripartite synapse consisting of the conventional synapse ensheathed by astrocyte processes together serve as models for neuroglial interactions. Indeed, evidence from astrocyte-neuron co-cultures has demonstrated that the presence of astrocytes in neuronal cultures increases the number of synapses and their efficiency. On the other hand, gap junctional communication and function can

be regulated by neurons (Rouach et al., 2004). It is now generally accepted that astrocytes are likely involved in a variety of neurodegenerative diseases; however, alterations in the gap junction communication in pathological conditions, regulation of hemichannels and connexin expression and function is largely unresolved (Nakase and Naus, 2004).

8.4.3.3.2. Role of Calcium

While neurons are most prominently identified with their electrical excitability and astrocytes lack such electrical impulses, calcium waves that propagate through gap junctions have emerged as the parallel mechanism to that of the transfer of electrical impulse from one neuron to another. This of course by no means suggests that calcium communication is unique to astrocytes; indeed, such signals are commonly used by a variety of cells and neurons are no exception to this. In neurons, calcium signals lead to an instant integrated electrical and chemical communication in synaptic cells. In both cultured astrocytes and astrocytes in intact brain slices, excitation of one cell can form a calcium wave transferred to several neighboring cells in multiple directions. This involves elevated calcium in a single cell followed by elevated intra-

FIGURE 8.2. The astrocyte nexus: The astrocyte processes engulf the synapse forming what is now known as the tripartite synapse, consisting of pre- and post-synaptic elements as the two components along with the astrocyte ensheathment as the third. The brain astrocytes communicate with each other through intercellular connections forming a large network on interconnected cells. These cells join through gap junctions that form a channel through which small molecules can pass from one cell to the next. Calcium, one of the molecules that can pass through these gap junctions can lead to exponential transfers within the astrocyte nexus forming a calcium wave. Such connexin 43 containing functional gap junctions are primarily observed in the astrocytes in the brain.

cellular calcium in other cells. Such transfer of the calcium wave has been related to the Cx43 gap junction coupling of astrocytes both in vitro and in situ (Schipke and Kettenmann, 2004). Mobilization of intracellular calcium is also widely used by astrocytes as a prominent cell signaling mechanism in response to a variety of stimuli both in physiological and pathological conditions (Verkhratsky and Kettenmann, 1996). Calcium ions form an important cellular messenger and can provide an exquisitely sensitive mechanism for signaling, depending on their amount, distribution, amplitudes, and time course.

Even more exciting is that neuronal activity can stimulate such calcium communication in astrocytes and vice versa (Perea and Araque, 2005a). Thus, the role of calcium in the function of the tripartite synapse has received significant recent attention (Araque and Perea, 2004; Hirrlinger et al., 2004; Perea and Araque, 2005b). Ca^{2+} excitability of glia is observed in response to a variety of stimuli (Verkhratsky and Kettenmann, 1996). Such an elevation in intracellular calcium in a single astrocyte thus leads to the elevated calcium in the neighboring cells or the calcium wave described above. The complexity of calcium regulation in astrocytes is even greater, as has been revealed by recent studies showing that the calcium oscillations in a single cell may not even encompass the entire cell volume, but remain restricted to certain microdomains or certain processes within the astrocyte. Thus, we see the beauty of the autonomous functioning of a specific part of the cell that may have encompassed a syncytium of other cells or may ensheath certain synapses, and provide at the same time the possibility of chemical coupling of the entire cell when given the appropriate stimulus (Carmignoto and Pozzan, 2002; Kettenmann and Filippov, 2002; Nett and McCarthy, 2002). The question as to what such calcium excitability of glia does in the neuroglial interactions is evolving. Certainly, from the example set by neurons where calcium signaling is tightly integrated with chemical release, the possibility that calcium excitability of astrocytes leads to the release of metabolites, which may in turn act in an autocrine or a paracrine manner, has also been investigated. The arena of calcium excitability of glia, their functional syncytium in the brain and their role in the tripartite synapse, all are subjects of intense investigation and will prove valuable in the complete understanding of neuroglial function.

8.4.3.4. *Releasing Neuropeptides and Neurotrophins*

Apart from its function as “support” cells by maintaining integrity of the CNS, astrocytes release several neuropeptides and neurotrophins. So far, four families of neuropeptides have been demonstrated to be expressed in astrocytes:

- A. *Renin-angiotensin family*: The major function of renin-angiotensin system (RAS) in periphery is to maintain body-fluid homeostasis and regulate blood pressure.
- B. *Endothelins*: Endothelins (ETs), a group of vasoactive peptides, acts as growth factor, exerting different functions like induction of proliferation, protein synthesis or changes

in morphology. The ET1 also increases the rate of glucose 6-phosphate utilization via pentose phosphate pathway.

C. *Enkephalins*: The pentapeptide enkephalins are the ligand of orphan receptors in brain and are present mostly as precursor form in astrocytes.

D. *Neurotrophins*: Astrocytes are capable of releasing several growth factors and neurotrophic factors including epidermal growth factor (EGF), transforming growth factor (TGF), insulin like growth factor-1 (IGF-1), fibroblast growth factor-2 (FGF-2), brain-derived neurotrophic factor (BDNF), glial-derived neurotrophic factor (GDNF), and neurotrophin-3 (NT-3) (Wu et al., 2004).

8.4.3.5. *Facilitating Neurogenesis*

One of the key advances in the field of neurobiology is the discovery that astroglial cells can generate neurons not only during development, but also throughout adult life and potentially even after brain lesion. It has been shown that in neurogenic regions of adult brain (ventricular zone, hippocampus, and olfactory subependyma), astrocytes secrete factors like FGF-2, IGF-1, Shh, BDNF, GDNF, and NT-3 that induce neurogenesis (Altaba et al., 2002) and support the growth of neurons and neural progenitor cells (Wu et al., 2004).

8.4.4. *Role of Astrocytes in CNS Disorders*

8.4.4.1. *Activation of Astrocytes and Gliosis*

Recent evidence suggests that astrocytes might act as immunocompetent cells within the brain (Shrikant and Benveniste, 1996). Astrocytes react to various neurodegenerative insults rapidly, leading to vigorous astrogliosis. This reactive gliosis is associated with alteration in morphology and structure of activated astrocytes along with its functional characteristics (Eddleston and Mucke, 1993). The astrocytic processes construct a bushy network surrounding the injury site, thus secluding the affected part from the rest of the CNS area. Subsequently, astrogliosis has been implicated in the pathogenesis of a variety of neurodegenerative diseases, including Alzheimer's disease (AD), Parkinson's disease, inflammatory demyelinating diseases, HIV-associated dementia (HAD), acute traumatic brain injury, and prion-associated spongiform encephalopathies (Eng and Ghirnikar, 1994). Although activated astrocytes secrete different neurotrophic factors for neuronal survival, it is believed that rapid and severe activation augments/initiates inflammatory response leading to neuronal death and brain injury (Tani et al., 1996; Yu et al., 1993). Enhanced up-regulation of GFAP is considered as a marker for astrogliosis (Eng et al., 1994). GFAP increases at the periphery of ischemic lesion following neurodegenerative insults (Chen et al., 1993). Senile plaques, a pathologic hallmark of Alzheimer's disease, are associated with GFAP-positive activated astrocytes (Nagele et al., 2004). It is reported that in various neuroinflammatory diseases, the increased GFAP expression corresponds to the severity of astroglial activation (Eng et al., 1992; Eng and Ghirnikar, 1994).

Recently our lab showed that various neurotoxins increase the expression of GFAP in astrocytes via nitric oxide (NO) (Brahmachari et al., 2006) suggesting that scavenging of NO may be an important mechanism in attenuating astrogliosis. Although the activation of NF- κ B is involved in neurotoxin-induced production of NO in astrocytes, once NO is produced, it does not require the activation of NF- κ B to induce the expression of GFAP (Figure 8.3). However, NO induces/increases the expression of GFAP in astrocytes via guanylate cyclase (GUCY)—cyclic GMP (cGMP)—protein kinase G (PKG) pathway (Figure 8.3).

8.4.4.2. Release of Pro-inflammatory Molecules

Upon severe activation in response to various neurodegenerative and neuroinflammatory challenges, astrocytes secrete various pro-inflammatory molecules including pro-inflammatory cytokines (TNF- α , IL-1 α , IL-1 β , IL-6, and lymphotoxin), chemokines, reactive oxygen species, reactive nitrogen species, and eicosanoids (Brosnan et al., 1994; Gendelman et al., 1994; Meeuwsen et al., 2003; Van Wagoner et al., 1999). These secreted pro-inflammatory molecules play an important role in the pathogenesis of various neurological disorders (Heales et al., 2004). In cultured murine astrocytes, bacterial lipopolysaccharides (LPS) act as a prototype inducer of various inflammatory responses. LPS is capable of inducing the expression of pro-inflammatory cytokines and inducible nitric oxide synthase (iNOS) in rat primary astrocytes (Pahan et al., 1997) but unable to induce the expression of iNOS in human astrocytes (Jana et al., 2005).

Among different pro-inflammatory cytokines (IL-1 β , TNF- α , and IFN- γ) tested, only IL-1 β alone is capable of inducing iNOS in human primary astrocytes (Jana et al., 2005). Similarly, among different cytokine combinations, the combinations involving only IL-1 β as a partner are capable of inducing iNOS in human astrocytes (Figure 8.4). The combination of IL-1 β and IFN- γ induces the expression of iNOS at the highest level in human astrocytes. Different pro-inflammatory transcription factors are involved in the transcription of iNOS in various cell types including astrocytes (Kristof et al., 2001; Liu et al., 2002; Pahan et al., 2002; Xie et al., 1994). All the three cytokines independently induce the activation of AP-1 while IL-1 β and TNF- α but not IFN- γ induces the activation of NF- κ B. However, among three cytokines, only IL-1 β is capable of inducing the activation of CCAAT box/enhancer-binding protein β (C/EBP β) (Figure 8.4) suggesting an essential role of C/EBP β in the expression of iNOS in human primary astrocytes (Jana et al., 2005). In addition to pro-inflammatory cytokines, viral double-stranded RNA (Auch et al., 2004) and HIV-1 Tat also induce the expression of iNOS and the production of NO in human astrocytes (Liu et al., 2002).

8.4.4.3. Do astrocytes Present Antigen Under Autoimmune Response?

The CNS has long been known as “immunological privileged site” as it is secluded by BBB from peripheral immune system. However, this hypothesis is gradually becoming wrong. Microglia are capable of functioning as antigen-presenting cells (APC) as they express MHC I and II molecules (Carpentier et al.,

FIGURE 8.3. Various neurotoxins induce the expression of inducible nitric oxide synthase (iNOS) via the activation of NF- κ B. Nitric oxide produced from iNOS then induces the activation of guanylate cyclase (GUCY) that catalyzes the production of cGMP. Inhibition of phosphodiesterase may also increase the level of cGMP. Cyclic GMP utilizes protein kinase G (PKG). Cyclic GMP utilizes protein kinase G (PKG) to increase the expression of GFAP. IL-1R, IL-1 receptor; TLR4, toll-like receptor4; GPCR, G protein-coupled receptor; TLR3, toll-like receptor 3.

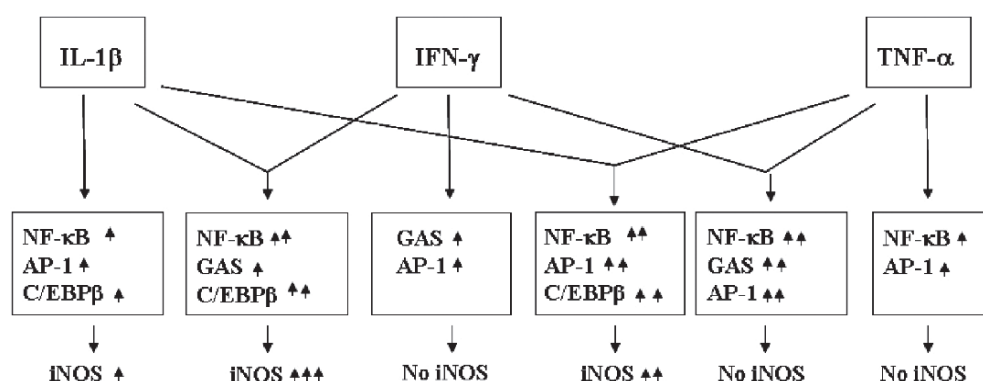

FIGURE 8.4. Expression of iNOS by various pro-inflammatory cytokines in human primary astrocytes. TNF- α and IFN- γ alone or in combination are unable to induce the expression of iNOS. On the other hand, IL-1 β alone or in combination with other cytokines induce iNOS in human astrocytes. Activation of AP-1 and GAS together by IFN- γ is not sufficient for the expression of iNOS. Activation of AP-1 and NF- κ B together by TNF- α is also not sufficient for iNOS expression. Activation of AP-1, NF- κ B and GAS together even at a higher level by the combination of TNF- α and IFN- γ compared to that induced by individual cytokines is also not sufficient for the expression of iNOS. However, IL-1 β capable of activating C/EBP β , AP-1 and NF- κ B induced iNOS in human astrocytes suggesting an important role of C/EBP β in the expression of iNOS in human astrocytes.

2005; Dong and Benveniste, 2001). In addition, microglia also expresses co-stimulatory molecules B7.1 and B7.2 molecules which play a role during antigen presentation. Another possible candidate as CNS APC is astrocyte. Expression of MHC II in astrocyte upon stimulation with IFN- γ or viruses has been demonstrated both *in vivo* and *in vitro*. However, capability of astrocytes as APC is still a controversial point. Examination of CNS tissues in MS, shows expression of B7-1 or B7-2 co-stimulatory molecules on macrophages and microglia but not on astrocytes. Human astrocytes also do not express co-stimulatory molecules B7-1 or B7-2. On the other hand, murine astrocytes express B7-1 or B7-2 either constitutively or in the presence of IFN- γ . Conflicting results are also found in case of CD40 expression. For example, CD40 expression is observed in fetal human astrocytes but not in adult human astrocytes. Therefore, functional ability of astrocytes as APC needs more research.

8.4.4.4. Formation of Glial Scar:

A Double-Edged Sword

Astrocytes play a dual role in inflammatory insults. In one hand, activated astrocytes, characterized by cellular hypertrophy, proliferation and increased GFAP expression represent anisomorphic gliosis. This is the consequence of gross tissue damage and results in the formation of tightly compacted limiting glial margin termed as astrogliotic scar or glial scar. The pro-inflammatory molecules released by reactive astrocytes in the scar cause tissue damage and inhibit neurite outgrowth as well as induce oligodendrocytes death. Chondroitin and keratin sulphate proteoglycans are among the main inhibitory extracellular matrix molecules that are produced by reactive astrocytes in the glial scar and are believed to play a crucial part in failure to regeneration. On the other hand, isomorphic gliosis, formed in response to insult, results in improved recovery

and regeneration of the damaged tissue (Eddleston and Mucke, 1993; Silver and Miller, 2004). At the sites distant from injury, activated astrocytes get transformed to a more pronounced stellate shape with increased production of anti-oxidants and soluble growth factors that coordinate tissue remodeling in enhancing the survival of adjacent neurons and glia.

8.4.4.5. Trying to Defend Neurons Against Oxidative Stress and Excitotoxic Damage

One of the hallmarks of various neurodegenerative and neuroinflammatory disorders is oxidative stress-induced CNS damage. Such oxidative stress can damage lipids, proteins and nucleic acids of cells and power-house mitochondria causing cell death in assorted cell types including neurons and oligodendroglia. However, astrocytes having high levels of anti-oxidant enzymes (glutathione peroxidase, catalase, glutathione reductase, and superoxide dismutase) and anti-oxidants (glutathione and ascorbic acid) try to absorb reactive oxygen species ($O_2^{\cdot-}$, $O_2^{\cdot-}$, and OH^{\cdot}) and reactive nitrogen species (NO, ONOO $^-$), maintain redox homeostasis and defend the insulted CNS (Chen and Swanson 2003; Dringen and Hirrlinger, 2003; Wilson, 1997). In addition, astrocytes also scavenge detrimental molecules such as glutamate, produced during synaptic transmission through neurons (Hertz and Zielke, 2004). Astrocytes convert glutamate to glutamine by glutamine synthetase.

8.4.4.6. Swelling of Astrocytes

Astrocytes undergo rapid swelling in certain acute pathological conditions like ischemia and traumatic brain injury. Different mechanisms are involved in such swelling process of astrocytes. Some of these are, decreasing extracellular fluid osmolarity, intracellular acidosis, formation of ammonia, increase in Na^+ , K^+ , $2Cl^-$ co-transporter system, and due to drastically

elevated levels of arachidonic acid and its metabolites. Alteration in glutamate metabolism and accumulation of glutamine and its transamination product, alanine is another possible cause of astrocytes swelling. In ischemic condition or in acute brain trauma, proton accumulation in cytoplasm cause astroglial cell swelling predominantly via activation of Na^+/H^+ and $\text{Cl}^-/\text{HCO}_3^-$ exchangers.

8.4.4.7. Undergoing Apoptosis Under Acute Insults

Although astrocytes usually undergo proliferation and gliosis in various neurodegenerative disorders, under acute insults, astrocytes may undergo apoptosis. *Ex vivo* cell culture studies demonstrate that tumor suppressor protein p53 plays a role in neuronal as well as astrocyte apoptosis (Bonni et al., 2004). HIV-1 infection of the central nervous system (CNS) frequently causes dementia and other neurological disorders in which apoptosis of astrocytes along with neuron has been found. HIV-1 infection of primary brain cultures induces the receptor tyrosine kinase c-kit and causes apoptosis of brain cells including astrocytes (He et al., 1997). The importance of c-Kit in apoptosis of astrocytes has further been confirmed by overexpressing c-Kit in an astrocyte-derived cell line in the absence of HIV-1. The mechanism of c-kit induction by HIV-1 involves transactivation of the c-kit promoter by the HIV-1 Nef protein.

8.5. Oligodendrocytes: Biology and Function

Camillo Golgi was the first to give a good description of glia. A few years later, Cajal, student of Rio Hortega (1921) showed that there are two quite distinct cell types of neuroglia besides astrocytes using silver carbonate impregnation technique which he named oligodendrocyte (OL) and microglia. OLs are specifically the myelin-forming cells of the CNS.

8.5.1. Markers and Morphological Characteristics of Various Developmental Stages of Oligodendrocytes

Among different brain cells, the development of OL has been well characterized. During differentiation, oligodendrocyte lineage cells (early oligodendrocyte progenitors, oligodendrocyte progenitors, pro-oligodendrocytes, immature oligodendrocytes, and mature oligodendrocytes) (Figure 8.5) express stage-specific components that serve as markers of lineage progression (Table 8.2). Morphological characteristics of various developmental stages are shown in Figure 8.5.

8.5.2. Biological Role of Oligodendrocytes in the CNS

The major biological role of OL is myelination. However, OL may also promote neuronal survival, axonal growth and process formation. Neuronal function is also influenced by OL-derived soluble factors that induce sodium channel-clustering along axons. Neurotrophins (NGF, BDNF, and NT3) produced from OL may provide the trophic support for both OL and local neurons.

PSA-NCAM, polysialylated form of neural cell adhesion molecule; PDGFR- α , platelet-derived growth factor receptor α ; MBP, myelin basic proteins; PLP, proteolipid protein; DM20, isoform of PLP; MOG, myelin/oligodendrocyte glycoprotein; MAG, myelin-associated glycoprotein; CNPase, 2',3'-cyclic nucleotide 3'-phosphodiesterase (Baumann and Pham-Dinh, 2001; Deng and Poretz, 2003).

8.5.2.1. Myelinating CNS Neurons

Myelination is a sequential multi-step process in which a myelinating cell recognizes and adheres to an axon, then ensheathes, wraps and ultimately excludes its cytoplasm from the spiraling process to form compact myelin. An OL is able to myelinate upto 40 axons depending on its localization. Myelin is composed of lipids and proteins, most of which are

FIGURE 8.5. Different stages of oligodendroglial development.

TABLE 8.2. Stage-specific markers of oligodendrocytes.

Developmental stages	Markers	Detection	Characterization
Precursor	PSA-NCAM, Nestin, PDGFR- α ,	Anti-PDGFR- α antibody	PSA-NCAM ⁺ /Nestin ⁺ /
A2B5 ⁻	DM-20		
Oligodendrocyte Progenitor cells(OPCs)	NG2/AN2+ proteoglycan, PDGFR- α protein or mRNA, GD3-related gangliosides, DM-20, CNPase	Anti-NG2 antibody, Anti-PDGFR- α antibody, A2B5 antibody	A2B5 ⁺ /O4 ⁻
Pro/pre-oligodendrocyte	PDGFR α , O4, GD3, NG2/AN2+, PLP/DM20, CNPase	Anti-NG2 antibody, Anti-PDGFR- α antibody, O4 antibody	A2B5 ⁺ /O4 ⁺
Immature oligodendrocytes	GalC, O4, CNPase, PLP/DM20	O4, O1, CNPase	A2B5-/MBP-/R-mAb+
Mature oligodendrocytes	GalC, O4, CNPase, MBP, PLP, MAG, MOG	MBP, MOG, PLP, MAG	A2B5-/MBP+

specific for the myelin sheath. The major proteins are MBP, PLP, CNPase, and MAG. In the CNS, axonal factors play a critical role in the myelination process and thickness of the myelin, and that myelination in the CNS depends on a balance between positive and negative axonal signal (Sherman and Brophy, 2005).

8.5.2.1.1. Role of Proteins

Role of CNPase: CNPase was first identified in CNS myelin and it represents about 4% of the total myelin protein in the CNS. It possesses enzymatic activity that catalyses the hydrolysis of 2', 3'-cyclic nucleotides into their corresponding 2'-neucleotides. However, to date any substrates of this enzyme has not been detected in the brain. Therefore, precise role of this enzyme in brain is unknown. However, it is one of the earliest myelination-specific polypeptides, synthesized by oligodendrocytes prior to the appearance of the myelin structural proteins (MBP and PLP) and its synthesis persists into the adulthood, suggesting a role in the synthesis and maintains of the myelin sheath. Over-expression of CNPase in transgenic mice perturbs myelin formation and creates aberrant OL membrane expansion. Recently, CNP knockout mouse study shows that CNP protein is required for maintaining the integrity of para-nodes and disruption of the axo-glial signaling at this site causes the progressive axonal degeneration (Rasband et al., 2005).

Role of MBP: MBP is one of the major proteins of the CNS, and it constitute about 25–30% of the total protein. The 18.5 kDa isoform of myelin basic protein (MBP) is the exemplar of the family, being most abundant in adult myelin, and thus the most-studied. Shiverer mutation of MBP gene results in the absence of MBP proteins and morphological analysis of the CNS reveals an almost total lack of myelin in the brain, and also the existing myelin is abnormal, presenting no major dense line. Therefore, MBP is necessary for the formation of the major dense line in the CNS myelin (Readhead and Hood, 1990).

Role of MOG: MOG is a member of the immunoglobulin super family, preferentially localized on the outside surface of myelin sheath and on the surface of OL process. Immunocy-

tochemical studies demonstrate that the expression of MOG is late in OL differentiation compared with other major myelin proteins. It is used as a surface marker of oligodendrocyte maturation. This specific CNS protein is a minor component of myelin, constituting 0.01–0.05% of total myelin proteins. It is a 26–28 kDa integral glycoprotein and like other myelin proteins it may exist in multiple forms. Since the location of this protein in outermost surface of the myelin, it is easily accessible to a humoral immune response. MOG not only binds C1q but also may be the protein in myelin responsible for complement activation (Johns and Bernard, 1999).

Role of PLP/DM20: PLP is the most abundant intra-membrane protein and represents about 50–60% of the total protein in the CNS. It is localized predominantly in compact myelin. DM-20 and PLP arise from alternative splicing of a genomic transcript and differ by a hydrophilic peptide segment of 35-amino acids long, the presence of which generates the PLP product. PLP is necessary for normal myelin compaction, but the molecular mechanism for the adhesive function of these proteins is not known. In addition, it has been shown that PLP/DM20 play a metabolic role in maintaining axonal metabolism (Knapp, 1996) and also play an important role in the formation of intraperiod line and in maintaining axonal integrity. In human, mutation of PLP and DM20 gene causes Pelizaeus-Merzbacher disease (PMD), an X-linked dysmyelinating neuropathy, and spastic paraplegia type II (SPG-II) (Duncan, 2005).

Role of other myelin proteins: Besides these four proteins, myelin also contains other proteins that play a critical role in myelin compaction and neuronal function.

Myelin-associated glycoprotein (MAG): MAG is a minor constituent of both the CNS and PNS myelin. MAG found on the myelin membrane adjacent to the axon. MAG is believed to participate in axonal recognition and adhesion, inter-membrane spacing, signal transduction during glial cell differentiation, regulation of neurite out growth, and in the maintenance of myelin integrity.

Myelin associated/oligodendrocyte basic protein (MOBP): MOBP is abundantly expressed in the CNS myelin and shares several characteristics with MBP. MOBP is synthesized by mature OL and localized at the major dense line, suggesting a role in the myelin compaction process.

P2: P2, a basic protein with a molecular weight about 13.5 kDa, is located on the cytoplasmic side of the compact myelin membranes. It may serve as lipid carrier and thus could be involved in the assembly, remodeling and maintenance of myelin (Garbay et al., 2000).

Oligodendrocyte-specific protein (OSP/claudin-11): OSP/claudin-11 and PLP are both tetraspan proteins concentrated in CNS myelin. OSP represents about 7% of total myelin proteins. They possibly play an important role in myelin formation and maintenance due to their localization and concentration in membrane sheaths. Individual OSP/claudin-11- and PLP-null mice have relatively normal-appearing myelin and mild neurological deficits due to their compensatory role. However, when both OSP/claudin-11 and PLP genes are knocked out, mice show severe neurological deficits, markedly abnormal myelin compaction, and smaller axon diameters (Chow et al., 2005).

Cx32: Cx32, an integral membrane protein, is structurally related to PMP22 with four hydrophobic transmembrane domains. Recent studies show that it is also expressed on some areas of the CNS myelin and corresponding myelinating OL. Cx32 is preferentially expressed in oligodendrocytes in the CNS and in Schwann cells in the PNS. In addition to forming gap junctional channels, Cx32 also forms functional hemichannels. Mutation in Cx32 causes a common peripheral demyelinating neuropathy, X-linked Charcot-Marie-Tooth disease (Gomez-Hernandez et al., 2003).

Oligodendrocyte-myelin glycoprotein (OMgp): It is a glycosylated protein with molecular mass 120 kDa. It is located in the para-nodal areas of myelin. During injury, it inhibits the axonal growth by interacting with Nogo-66 receptor (NgR) complex.

Myelin/oligodendrocyte specific protein (MOSP): MOSP is a novel surface protein which is exclusively expressed in CNS myelin. It also plays an important role in membrane/cytoskeleton interactions during the formation and maintenance of CNS myelin.

8.5.2.1.2. Role of Lipids

In the CNS, lipids play an important role in myelin formation along with various protein molecules. One of the major biochemical characteristics that distinguish myelin from other biological membranes is its' high lipid-to-protein ratio. About 70–80% of the dry weight of myelin is comprised of lipid components and 20–30% protein. In every mammalian species, myelin contains cholesterol, phospholipids and glycolipids in molar ratios ranging from 4:3:2 to 4:4:2. In mature brain, cholesterol is the major lipid in myelin (about 20–25%) but generally normal myelin does not contain any cholesterol

ester. Cholesterol helps to increase membrane thickness and fluidity as well as ion leakage through membranes which may be relevant to its property of electrical insulation.

Other abundant lipids in myelin are galactosylcerebrosides (Gal-C) and their sulfated derivatives (sulfatides). GalC represent 20% lipid dry weight in mature myelin. Immunological and chemical perturbation studies indicate that these lipids are involved in oligodendrocyte differentiation, myelin formation and myelin stability. These galactolipid-deficient animals exhibit severe tremor, hindlimb paralysis and display electrophysiological deficits in both CNS and PNS (Baumann and Pham-Dinh, 2001).

8.5.2.1.3. Molecules Involved in Positive and Negative Regulation of Myelination

The formation and maintenance of the myelin sheath require the coordination of a number of gene products. While some gene products facilitate myelination, some others try to suppress myelin formation. In the following lines, we describe such positive and negative regulatory mechanisms.

Molecules involved in positive regulation of myelination: OLIG1 and OLIG2 are closely related basic helix-loop-helix transcription factors that are expressed in myelinating OL and their progenitor cells in the developing CNS. Both OLIG1 and OLIG2 are positive regulators of myelination. Specifically OLIG1 has an essential role in oligodendrocyte differentiation and myelination, as it regulates the transcription of major myelin-specific genes MBP, PLP and MAG. On the other hand, OLIG2 is required for the initiation of oligodendroglialogenesis but its role in myelination is controversial (Xin et al., 2005).

Another important molecule that stimulates myelination is GPI-linked neural cell recognition molecule F3/contactin. This is a physiological ligand of Notch that signals via DTX1 to promote the development of OL (Hu et al., 2003; Popko, 2003). Additionally, F3 also transduces signals to glial intracellular Fyn, which then interacts with Tau protein to mediate myelination. As expected, different neurotrophins also favor myelination through the maintenance of oligodendroglial cell health and viability. For example, neurotrophin-3 (NT3) is known to induce both survival and proliferation of oligodendrocytes. NT3 interacts with TrkC to activate CREB that plays a critical role in proliferation and maturation of OPCs, and in the expression of myelin genes (MBP, P2, P0 MOG, PLP, and MAG) and anti-apoptotic gene Bcl-2. In addition, recent studies have identified many other molecules (e.g. PAX3, PPAR- δ , MyT1, SOX, GTX, Sp1, SCIP/Oct6/Tst-1) that may function as positive regulators of myelination (Wegner, 2000).

Molecules involved in negative regulation of myelination: Bone morphogenic proteins (BMP4s) should have a role in regulating bone density! Yes, they do have and in addition, these important molecules also regulate oligodendrocyte development. At early stage, BMPs regulate cell lineage decision and at later stage, they inhibit cell specialization in OL. For example, BMP4

signaling inhibits the generation of OL and enhances the generation of astrocytes from neural progenitor cells both *in vitro* and *in vivo*. BMP4 induces the expression of all four members of the inhibitor of differentiation (ID) family of helix-loop-helix transcriptional inhibitors and blocks oligodendrocyte lineage commitment through the interaction with OLIG1 and OLIG2 (Samanta and Kessler, 2004).

LINGO-1, a transmembrane protein containing a leucine-rich repeat (LRR) and immunoglobulin domain, functions as a component of the NgR1/p75 and NgR1/Taj (Troy) signaling complexes. Recent studies show that LINGO1 is also expressed in OL where it negatively regulates oligodendrocyte differentiation and axonal myelination by down-regulating the function of Fyn kinase and up-regulating the activity of RhoA-GTPase. Lack of LINGO-1 expression promotes more axonal myelination due to increased expression of myelin gene such as MBP, CNPase and MOG in OL. LINGO-1 knockout mice also show earlier onset of CNS myelination (Mi et al., 2005).

8.5.3. Fate of OL in CNS Pathology

Death of OL and subsequent myelin loss has been reported in a variety of myelin disorders including, multiple sclerosis (MS), X-adrenoleukodystrophy (X-ALD), adrenomyeloneuropathy (AMN), vascular dementia, periventricular leukomalacia (PVL), hypoxia, and ischemia. Several factors that might be associated with OL death in these pathophysiological conditions are discussed below.

8.5.3.1. Role of Autoimmune Trigger in the Death of OL

MS and experimental allergic encephalomyelitis (EAE), an animal model of MS, are autoimmune diseases of the CNS mediated by T cells recognizing self-myelin proteins including MBP, MOG, and PLP. T cells are activated in the periphery by unknown antigens of both myelin and non-myelin origins. After activation, T cells cross the blood-brain barrier and invade into the brain where they accumulate and proliferate in response to antigen re-stimulation. These activated T cells secrete different pro-inflammatory molecules which stimulate not only the resident glial cells (microglia and astroglia) but also other infiltrating cells. CD4⁺ and $\gamma\delta$ T cells express Fas-L which is found to be associated with oligodendroglial death. Furthermore, infiltrating CD8⁺ T cells interact with MHC class I surface receptor of OL and in turn cause oligodendroglial lysis. T cell-derived perforin may also be responsible for oligodendroglial death (Scolding et al., 1990).

8.5.3.2. Role of Cytokines in the Death of OL

Cytokines are important mediators in the inflammatory demyelination observed in MS, EAE, X-adrenoleukodystrophy (X-ALD), and Theiler's virus infection. In these pathologies, pro-inflammatory cytokines and others factors released by endogenous glial cells and/or infiltrated macrophages and CD4⁺ Th1 cells, accumulate and exert pleiotropic effects on

OL. At lower concentrations, these cytokine may be involved in normal development of the nervous system while following brain trauma or inflammatory insults, the overproduction of these cytokines may result in a homeostatic imbalance and may contribute to the outcome of the pathological event. Various cytokines can directly kill OL or it may also affect other signaling pathways that could be involved in the susceptibility of OL. For example, IFN- γ produced by T cells may induce oligodendroglial apoptosis and cell death via JAK-STAT pathway. Another pro-inflammatory cytokine TNF- α induces oligodendroglial death via death signaling pathways (e.g. death inducing signaling complex (DISC), ceramide signaling pathway and stress-activated protein kinase pathways (SAPK) (Buntinx et al., 2004). IL-1 is a strong stimulus for TNF- α release from astrocytes and microglia. Both IL-1 and TNF- α are capable of inhibiting the expression of myelin genes via redox-sensitive mechanism (Jana and Pahan, 2005).

8.5.3.3. Role of Nitric Oxide in the Death of OL

Nitric oxide (NO), a short-lived and highly reactive free radical, is an important physiological messenger in the CNS. However, high level of NO in the CNS has been associated with different type of neurodegenerative diseases such as MS and EAE. During CNS inflammation, activated microglia, astrocytes and infiltrating cells express inducible nitric oxide synthase (iNOS) producing excessive amount of NO. OL at different stages of differentiation are differentially sensitive to NO. For example, OPCs and immature oligodendrocytes are more susceptible than mature OL to NO. However underlying mechanisms are poorly understood. It has been shown that NO reacts with superoxide generated by NADPH oxidase from activated glial cells and infiltrating cells to form peroxynitrite, the most reactive NO derivative. This peroxynitrite plays a critical role in the death of OL (Li et al., 2005).

8.5.3.4. Role of Oxidative Stress in the Death of OL

Reactive oxygen species (ROS) and reactive nitrogen species (RNS) leading to oxidative stress have been implicated as mediators of demyelination and axonal damage in both MS and EAE. Oxidative stress can damage lipids, proteins and nucleic acids of cells and mitochondria potentially causing OL cell death. During oxidative stress-induced oligodendroglial apoptosis, cytochrome c is released from damaged mitochondria, which in turn leads to the activation of the death-related caspases 3 and 9. Another study by Vollgraf et al. (1999) shows that mature OL exposed to oxidative stress undergo chromatin segmentation, condensation via mechanisms involving transcriptional activation of the immediate early stress genes (c-fos and c-jun). An induction of Bax protein has also been reported under oxidative stress condition in OL (Mronga et al., 2004).

8.5.3.5. Role of Ceramide in the Death of OL

Ceramide, the lipid second messenger and a hydrolyzed product of sphingomyelin, is involved in apoptosis of OL. In

pathological conditions, pro-inflammatory cytokines (TNF- α and IL-1 β) released specifically from activated microglia and astroglia leads to the activation of sphingomyelinases and production of ceramide in OL via the redox-sensitive mechanism (Singh et al., 1998). Furthermore, a direct role of oxidative stress-induced ceramide production via activation of neutral sphingomyelinase has been recently demonstrated in OL. During Alzheimer's disease, amyloid- β is aggregated in the plaque region that also causes OL death by activating the NSMase-ceramide cascade via redox-sensitive pathways (Lee et al., 2004). In addition, ceramide can inhibit inwardly rectifying K⁺ currents and cause depolarization in OL (Hida et al., 1998).

8.5.4. Regeneration of OL

Recent evidences indicate that OPs remain intact both in normal white matter and in demyelinating CNS of patients with MS. OPs can give rise to new OL in experimental conditions and have the ability to repopulate areas from where they are missing (Franklin, 2002).

8.5.4.1. Molecules Involved in the Regeneration of OL

Recent identification of several genes associated with regeneration of OL has become helpful to understand the mechanism of remyelination and formulate a strategy for possible therapeutic intervention in demyelinating disorders. It has been shown that during demyelination, the expression of several genes such as, Nkx2.2, Olig1, Olig2, BMP4, and Fyn are increased in OPs (Lubetzki et al., 2005). Although functions of each of these genes are not clearly understood, some of these genes may lead to differentiation of the quiescent OPs to mature remyelinating OL and help oligodendrocyte regeneration in demyelinated areas (Zhao et al., 2005).

8.5.4.2. Role of Schwann Cells in the Regeneration of OL

During demyelination, after macrophages/microglia remove myelin debris and glial scar, SCs enter into the CNS where they remyelinate axons in the absence of reactive astrocytes. During this period, survival of SCs requires the axon-derived trophic factors (Zhao et al., 2005). Schwann cell can also produce some growth factors like IGF1, FGF2 and PDGF, which promote the migration of OPs and maturation into myelinating OL.

8.5.4.3. Role of Thyroid Hormone in the Regeneration of OL

Thyroid hormone (TH) plays an important role by regulating several stages of oligodendrocyte development and maturation. Oligodendrocytes express TH receptors and during demyelination, TH increases the expression of NGF. This NGF, in turn may lead to an increase in maturation of OPs and remyelination through the activation of Notch-Jagged signaling pathway. TH hormone also up-regulates the expression of PDGFR- α , MBP and CNPase in CNS tissues of animals with MS (Calza et al., 2005).

8.6. Schwann Cells (SCs): Peripheral Glia

The peripheral nervous system contains a number of distinct glial cells, each of which is intimately associated with different parts of the neurons or with specific neuronal cell types. Earlier, these cells were known as the supporting cells of the PNS but recent studies delineate their multifunctional role. These cells are of two types: satellite cells and Schwann cells (SCs). Satellite cells surround the neuronal cell bodies in dorsal root sensory ganglia and in sympathetic and parasympathetic ganglia. These cells help to maintain a controlled microenvironment around the nerve cell body, providing electrical insulation and a pathway for metabolic exchange. The other cells named after German physiologist Schwann are flattened cells with an elongated nucleus oriented longitudinally along the nerve fiber. Surface of all axons in peripheral nerves are ensheathed by non-myelinating or myelinating SCs.

8.6.1. Classification of Schwann Cells (SCs)

In the mature nervous system, SCs can be divided into three classes based on their morphology, biochemistry and function: myelinating Schwann cells (MSCs), non-myelinating Schwann cells (NMSCs) and perisynaptic Schwann cells (PSCs) (Figure 8.6).

MSCs are well characterized and they wrap around axons with a diameter of 1 μ m or greater, including all motor neurons and some sensory neurons. This is a mystery why they wrap a specific diameter of the axons. Smaller diameter axons including many sensory and all post-ganglionic sympathetic neurons are myelinated by NMSCs. The NMSCs provide the metabolic and mechanical support to the axon. The NMSCs appear latter than MSCs. They express higher levels of GFAP, p75NTR and cell adhesion molecule L1 compare to MSC. The PSCs located at the neuromuscular junction incompletely wrap around the pre-synaptic terminal of motor axons. They help to maintain a stability of the neuromuscular junction and regulate synaptic transmission (Corfas et al., 2004).

8.6.2. Schwann Cell Development

SCs originate from the neural crest cells, a transient population of cells migrating away from the dorsal part of the neural tube. The signaling pathway and their detailed migratory route are not clearly known. Neural Crest cells are multipotent cells that differentiate to form neurons and glia of the PNS, and also additional cell and tissue types such as melanocytes and connective tissue of the head. Several molecules (e.g. ErbB3, transcription factor SOX10, AP2 α and Ets1, the N-Cadherin 6, the low affinity receptor for nerve growth factor p75NTR) have been shown to play important roles during the detachment of neural crest from neural tube (Jessen and Mirsky, 2005).

Markers of lineage progression: Characterization of a number of specific biochemical markers has increased our knowledge on the stages of SC maturation, both *in vivo* and *in vitro*. Some of the biochemical markers have been shown to overlap partially (Table 8.3).

FIGURE 8.6. Different stages of Schwann cell development.

TABLE 8.3. Stage-specific markers of Schwann cells.

Stages	Markers
Neural crest cells	SOX10, AP2 α
Schwann cell precursor (SCPs)	Cadherin19, AP2 α , low level P0, GAP43, F-spondin, SOX10, BFABP, DHH
Immature Schwann cells	S100 β , GFAP, low level of P0, SOX10, O4 antigen, BFABP, DHH
Myelinating Schwann cells	P0, PMP-22, MBP
Non-myelinating Schwann cells	NCAM, GFAP

SOX10, SRY (sex determining region Y) box 10; AP2 α , activator protein 2 α ; DHH, desert hedgehog; GAP43, growth associated protein 43; P0, protein zero; O4, lipid antigen; BFABP, brain fatty acid-binding protein; S100, calcium-binding protein; PMP22, peripheral 22kDa myelin protein, MBP, myelin basic protein; GFAP, glial fibrillary acidic protein; NCAM, neuronal cell-adhesion molecule.

SOX10, SRY (sex determining region Y) box 10; AP2 α , activator protein 2 α ; DHH, desert hedgehog; GAP43, growth associated protein 43; P0, protein zero; O4, lipid antigen; BFABP, brain fatty acid-binding protein; S100, calcium-binding protein; PMP22, peripheral 22kDa myelin protein, MBP, myelin basic protein; GFAP, glial fibrillary acidic protein; NCAM, neuronal cell-adhesion molecule.

8.6.3. Signaling Pathways Involved in Survival, Migration and Death of SCs

8.6.3.1. Survival

The survival of immature SCs in late embryonic and pre-natal nerves is probably controlled by a balance between factors that support survival and factors that cause death. Axon-derived neuregulin family (NRG-1, NRG-2, and NRG-3) have been implicated in the biological processes of SCs including fate specification, proliferation, survival, migration, regulating the extent of myelination, and triggering demyelination. It is believed that the interaction between several NRG ligands

with different ERB receptors (ErbB2, ErbB3, and ErbB4) on SCs plays a critical role in regulating these steps (Garratt et al., 2000; Michailov et al., 2004). SCs can support their own survival by producing a number of growth factors such as IGF2, NT3, PDGF- β , LIF, and lysophosphatidic acid (LPA) in an autocrine fashion. The autocrine survival circuits are probably important in maintaining the survival of SCs in injured nerves. However, SCPs may need some signal for their survival from neurons.

8.6.3.2. Migration

During development of the PNS, neural crest cells migrate along the outgrowing axons and proliferate in order to produce sufficient number of cells for myelination of axons. Various factors or signaling molecules present on the neighboring cells effect Schwann cell migration in cell culture and it is possible that these signals lead to SCs movements during radial sorting *in vivo*. Integrins, a subgroup of adhesion receptors mediate interaction between cytoplasm and the extracellular environment. This interaction influences the migration of neural crest cells, axonal out growth and SCs differentiation. Integrins can interact with different growth factors, cell adhesion molecules (NCAM and F3) and intracellular cytoskeleton or adaptors proteins. This interaction is crucial for conformational changes and movement of SCs. Several growth factors that regulate the migration of SCs include NRG1, BDNF, GDNF, NT3, and IGF-1. The majority of these molecules are also expressed by SC itself (Yamauchi et al., 2005; Iwase et al., 2005).

8.6.3.3. Death

NGF acting via the p75 neurotrophin receptor promotes cell death during the SC injury or infection via activation of c-jun-N-terminal kinase (JNK). It has been found that neonatal p75 neurotrophin receptor mutant mice are less prone to cell death after nerve transection. Here it is to be noted that the same neurotrophin signaling pathway may also promote survival of

SCs via activation of NF- κ B. Although mechanisms behind p75-mediated death of SCs are poorly understood, Yeiser et al. (2004) have shown that NGF signaling through the p75 receptor is deficient in TRAF-6 ($-/-$) mice and that NGF is unable to kill TRAF-6 ($-/-$) SCs. In addition, TGF β is also known to cause apoptosis of SCs via JNK in culture (Jessen and Mirsky, 2005).

8.6.4. Differences Between OL and SC

Although both OL and SC share the common task of synthesizing myelin, there are some differences between the two cell types. See Table 8.4.

8.6.5. Biological Roles

8.6.5.1. Myelinating Peripheral Neurons

SCs cover most part of the PNS neurons by myelin sheath. Although the PNS myelin is mainly formed by the differentiation of the plasma membrane of SCs, myelination of mammalian PNS is a very complex developmental process. It requires intricate timing of several gene expression and cellular interactions between the axon and differentiated SCs (Michailov et al., 2004). In the PNS, mature SCs express Dhh, a family member of the Hh signaling proteins that is involved in the formation of peripheral nerve sheath and is also responsible for the formation of nerve-tissue barrier. Therefore, it has been found that Dhh mutant mice are defective in nerve barrier formation and unable to protect themselves against inflammatory responses. The activity of Dhh is regulated by several molecules such as Notch1, Hes5, MASH-1, and others (Parmantier et al., 1999). Another protein NDRG1 that is abundantly expressed in the

cytoplasm of SCs rather than myelin sheath is also essential for maintenance of the myelin sheaths in peripheral nerves.

In addition, some well-known transcription factors such as, KROX20, NF- κ B, SOX10, OCT-6, and POU class 3 homeobox 2 (POU3F2) also play an important role in PNS myelination. KROX-20, a master regulator for myelinating SCs, appears to be fundamental in controlling SC differentiation, regulating the expression of a number of genes including periaxin, P0, MBP, and PMP22 by interacting with NAB (NGF1-A binding) proteins. Mutation of this transcription factor Krox-20 is associated with lethal human neuropathy such as congenital hypomyelinating neuropathy (CHN), Dejerine-Sottas syndrome (DSS) and the Charcot-Marie-Tooth (CMT) disease. OCT-6 and POU3F2 have been implicated in the expression of Krox-20 and may therefore positively regulate myelination (Ghislain and Charnay, 2006; Mattson, 2003).

8.6.5.2. Tissue Repair/Regeneration

The SCs play a pivotal role during the event of mechanical damage such as spinal or peripheral nerve injury due to their regenerative properties. SCs in the distal stumps of adult animals can survive for several months in the absence of axons due to injury/insult and these SCs provide both trophic factors and adhesive substrates that promote axonal regeneration and restore the original function. After nerve injury, SCs can transform their phenotype from differentiated myelinating state to the de-differentiating state. During this process, there is also up-regulation of regeneration-associated genes such as the neurotrophin receptor p75 NTR, neuregulin and their receptors (erbB2, erbB3, erbB4), and GAP-43. They also produce different trophic factors (GDNF, TGF- β , IGF-2, NT3, PDGF- β , and LIF), adhesion molecules (L1, NCAM), extra-cellular

TABLE 8.4. Differences between oligodendrocytes (OL) and Schwann cells (SC).

OL	SC
1. OLs are present only in the CNS.	1. SCs are the major glial cells in the PNS.
2. The sub ventricular zone (SVZ), which is present in late gestational and early post-natal mammalian brain, is a major source of OL.	2. SCs are originated from the neural crest.
3. Oligodendroglial developmental steps are irreversible.	3. Fully differentiated SCs retain an unusual plasticity throughout the life and can readily de-differentiate to form cells similar to immature SCs.
4. One oligodendrocyte extends several processes and can myelinate upto 1 to 40 axons with distinct internodes.	4. One SC has an intimate association with axon and each SC forms myelin around a single axon, and lines up along the axon to define a single internode.
5. GM4, one of the most abundant lipids of the CNS, is present in OL.	5. Some glycolipids such as sulfated glucuronyl paragloboside and its derivatives are specific to SC.
6. CNS myelin contains more choline and plasmalogens than PNS myelin (Garbay et al., 2000).	6. PNS myelin contains more ethanol phosphoglycerides than CNS myelin.
7. Basic proteins (MBP and PLP) are major constituents of CNS myelin (about 80% of the total protein) (Baumann and Pham-Dinh, 2001).	7. Glycoproteins (P0 and PMP22) are major constituents of PNS myelin.
8. OLs have phagocytic activity.	8. SCs do not have phagocytic activity.
9. OLs migrate slower and divide and remyelinate at a slower rate than SCs.	9. SCs migrate faster and divide and remyelinate at a faster rate than OLs.
10. OLs are less resistant than SCs to injury.	10. SCs are more resistant than OLs to injury.

matrix molecules (laminin, tenascin), proteoglycans, and collagen type IV in an autocrine/paracrine manner, thereby providing a favorable environment for axonal re-growth and their own survival (Jessen and Mirsky, 1999).

Summary

Astrocytes, OL and SC are not silent partners of others anymore as thought a couple of decades earlier. Recent works have put these cell types in the forefront of neuroscience research. Although astrocytes being the major cell type in the CNS get more attention than the other two cell types, both OL and SC play an equally important role in human health and disease through myelination of neurons in the CNS and PNS respectively. As a result, thousands of cutting-edge research articles are coming out each year describing biological and functional aspects of astrocytes, OL and SC. Therefore, now it is an uphill task to compile everything about these three important cell types in a single chapter. However, here we have made an honest attempt to briefly delineate major biological and functional aspects of these cell types. Although there are vast body of evidence that implicate dysfunction and dysregulation of astrocytes, OL and SC in a number of human neurological diseases, we are still more or less in the dark to draw an unifying picture from these data. An improved understanding of their genesis and function in both healthy and diseased conditions is necessary for better preservation of brain in physiological conditions and for better repairing of this organ in pathophysiological situations.

Review Questions/Problems

1. During developmental stage which cell types come last:
 - a. microglia
 - b. neuron
 - c. astrocyte
 - d. oligodendrocyte
2. If there is formation of abnormal Shh protein during embryogenesis:
 - a. genesis of astrocyte will be affected
 - b. genesis of oligodendrocytes will be affected
 - c. genesis of neurons will be affected
 - d. brain development will be impaired
 - e. all are true
 - f. none are true
3. Enzyme glutamine synthase is not found in
 - a. astrocytes
 - b. oligodendrocytes
 - c. none of the above is true
 - d. all are true
4. Tripartite synapse is formed by
 - a. neurons
 - b. microglia
 - c. astrocytes
 - d. microglia and astrocytes
 - e. neuron and astrocyte
5. In the central nervous system, major role of astrocyte is to
 - a. scavenge glutamine
 - b. scavenge cell debris
 - c. produce ATP
 - d. all the above
 - e. none the above
6. In the CNS, glycogen is found only in
 - a. oligodendrocyte
 - b. microglia
 - c. astrocyte
 - d. neuron
 - e. all the above
7. In astrogliosis, astrocytes form
 - a. cluster all around the CNS
 - b. bushy network surrounding the injury site
 - c. all are true
8. Schwann cells but not oligodendrocytes have phagocytic activity.
 - a. True
 - b. False
9. Unmyelinated axons generally have a smaller diameter than myelinated axons.
 - a. True
 - b. False
10. A single Schwann cell forms myelin around one and only one axon while a single oligodendrocyte forms myelin around several separate axons.
 - a. True
 - b. False
11. Oligodendrocytes progenitors are identified by A2B5 antibody whereas pre-oligodendrocytes are identified by O4 antibody.
 - a. True
 - b. False

12. Which of the sequential stage is correct for oligodendroglial development?

- a. Neural stem cells, progenitors, pre-oligodendrocytes, precursors and mature oligodendrocytes.
- b. Progenitors, precursors, pre-oligodendrocytes, mature oligodendrocytes and neural stem cells.
- c. Neural stem cells, precursors, progenitors, pre-oligodendrocytes and mature oligodendrocytes.
- d. Pre-oligodendrocytes, precursors, mature oligodendrocytes, progenitors and neural stem cells.
- e. None of the above.

13. Action potentials are conducted rapidly through (choose one)

- a. myelinated axons
- b. unmyelinated axons
- c. large diameter axons
- d. small diameter axon
- e. both a and c

14. Which of the following molecule is not a part of the peripheral nervous system?

- a. LINGO-1
- b. BDNF
- c. CNTF
- d. PDGF
- e. EGF

15. Which of the following functions in the nervous system is not provided by the oligodendrocytes?

- a. Ensheath axons
- b. Supply neurotrophic factors
- c. Form the node of Ranvier
- d. Phagocytic properties to remove debris.

16. Non-myelinating Schwann cell is characterized by the following properties EXCEPT

- a. Wraps axons greater than 1 μm .
- b. Appear later than myelinating Schwann cells.
- c. Myelinate all post-ganglionic sympathetic neurons.
- d. Produce more p75NTR and GFAP.
- e. Provide mechanical and metabolic support to the neuron.

17. Gliogenesis and Neurogenesis during development

- a. occur simultaneously during development
- b. follow this sequence i.e. gliogenesis followed by neurogenesis
- c. occur one after the other after the first is completed
- d. occur sequentially with overlapping periods

Macrophages, Microglia, and Dendritic Cells

Anuja Ghorpade, Howard E. Gendelman, and Jonathan Kipnis

Keywords Antigen presenting cells; Microglia; Mononuclear phagocytes; Oligodendrocytes glycoprotein; Neural progenitor cells; Neurodegeneration; Neuroprotection; Reactive oxygen species; Toll-like receptors

9.1. Introduction

Celebrated as the “decade of the brain,” the ten years between 1990 and 2000 gave rise to an increased awareness of brain function in health and disease. At the cellular level, none other than the microglia emerged as stars of the decade despite being only 10% of the total brain cell population. The profiles of microglia overpower, in part, neurons (Streit et al., 1999). In this chapter, we provide an overview of the diverse functions of microglia including their ontogeny, immune functions, and the spectrum of their responses during neurodegeneration. Microglia are the brain’s mononuclear phagocytes (MP) and are influenced by their microenvironment (Streit, 2006). Phagocytosis, killing, secretion of bioactive factors, and antigen presentation are function shared amongst all MP including microglia. Such roles in both health and disease are developed and discussed, in some detail, in this chapter.

9.2. MP Ontogeny

MP includes a family of terminally differentiated cells with shared innate immunological function such as monocytes, macrophages, dendritic cells (DC), and microglia (Flaris et al., 1993). Originally, macrophages were considered part of the reticuloendothelial system, which was in 1969 replaced by the current MP designation. Macrophages in Greek, means “big eaters” principally referring to their phagocytic function in nonspecific or innate defense [reviewed by Fujiwara (Fujiwara and Kobayashi, 2005)]. Cells originate from circulating monocytes to ingest and destroy cellular debris and pathogens as well as stimulating lymphocytes to respond to antigens.

The term macrophage, was used nearly a century ago by Elie Mechnikoff in 1882, when he discovered phagocytosis and explained its function, the first experimentally based theory in immunology. The concept was accepted in 1908 when Metchnikoff won the Nobel Prize and proved to be the first official recognition for the existence of immunology (Frolov, 1985). Nonetheless, it was nearly 12 years later when the contributions of W. Ford Robertson, Santiago Ramón y Cajal, Pio del Rio-Hortega, and Wilder Penfield developed the insights and discriminating histology that lead to the term microglia that was inevitably coined by del Rio-Hortega in 1919 (Kitamura, 1973). The word “mesoglia” was made for microglia in the beginning of the 20th century to dictate their unique origins as compared to neurons and macroglia. del Rio-Hortega was the one who conducted the first systematic studies on microglia and is considered the “father” of these cell types although F. Nissl and F. Robertson made earlier observations of the cell’s morphology. Many of Hortega’s observations are valid even today (Hortega, 1919, 1932) including the fact that resting microglia show characteristic elongated, almost bipolar cell bodies with spine-like processes.

The debate about the nature and identity of microglial cells has continued over several decades. In the 1980s, new immunohistochemical markers and lectins were discovered that provided microglia with improved histological characterization (Mannoj et al., 1986). It became clear with the advent of newer antigenic markers that microglia shared phenotypic characteristics and lineage-related properties with bone marrow-derived monocytes and macrophages of the MP-lineage system (Lee et al., 1992).

9.2.1. MP Differentiation and Development

Macrophages are renewed on an ongoing basis by the influx of monocytes from the circulation and by local division of immature MP that have arisen from precursors in the bone marrow. The cells develop from monoblasts to promonocytes then to circulating monocytes. During microbial infections and an inflammatory response monocyte production increases

from the bone marrow, a process regulated by colony stimulating factors produced from both macrophages and lymphocytes. The ontogeny of the macrophage are highly primitive and cells with MP properties can be found in the yolk sac (Moore and Metcalf, 1970). These cells express CD11b, the mannose receptor, and share other macrophage-like functions. In the bone marrow, the common myeloid precursor for macrophages and neutrophils is called colony forming unit-granulocyte macrophage (CFU-GM). This leads to the formation of monoblasts, the most immature cells of the MP system, which further develop into promonocytes and then monocytes. The newly formed monocytes remain in the bone marrow for about 24h and then enter the peripheral blood. Bone marrow progenitors give rise to monocytes, macrophages, and DC (van Furth, 1982). There is an established lineage relationship between macrophages and DC. These two cell types have in common essential roles in the development, differentiation, and maintenance of tissue homeostasis. Perhaps even more important is their shared roles in tolerance, and regulation of inflammation and immunological responses. Circulating monocytes can also give rise to several tissue-macrophages. Among the cells now recognized as being derived from a monocyte pool are histiocytes (in connective tissues), Kupffer cells (in the liver), osteoclasts (in the bone), microglial cells (in the brain), synovial type A cells, interdigitating cells, alveolar cells (in the lung), osteoclasts (in bone), and Langerhans cells (of the skin) (Nibbeling et al., 1987; Sluiter et al., 1987).

9.2.1.1. *Histological and Immunohistochemical Characterization of Monocytes and Macrophages*

Macrophages are generally large, irregularly shaped cells and contain a kidney-shaped or round nucleus (Figure 9.1). Monocytes usually have ample cytoplasm in contrast to lymphocytes. The surface of a macrophage is not smooth and presents a ruffled appearance. Differentiated cells usually bear microvilli that can be visualized with localization of vimentin, an MP-specific intermediate filament protein (Figure 9.1). Microglia, the resident central nervous system (CNS) macrophages, present a ramified morphology in the resting stages. Upon activation or injury, these cells can revert to an activated state and appear amoeboid in nature (Figure 9.1).

9.2.1.2. *Microglia*

Shown by lectin immunohistochemistry, microglia are present in the embryonic brain by 13 weeks of gestation (Billiards et al., 2006). Blood-borne monocytes migrate to the fetal brain and after the formation of blood–brain barrier, remain to form the resident population. There is functional and morphological variability in the microglia observed from 13 to 18 weeks of gestation indicating differential derivation (Chan et al., 2007). Ramified cells are found more in the cortex and amoeboid microglia, also known as brain macrophages, are found more in the germinal matrix. Moreover, in the first few weeks of the postnatal period, amoeboid microglia reduce in number giving

FIGURE 9.1. Morphological and immunohistochemical characteristics of monocytes and macrophages. Panel A demonstrates Wright's stain demonstrating the classical monocyte kidney-shaped nucleus. Panel B demonstrates the fine processes on microglial cells called the fimbriae. In the brain, microglial cells demonstrate a typical ramified phenotype as shown in panel C. In neuroinflammatory diseases, such as HAD, cells from the periphery infiltrate the brain as shown in panel D. A blood vessel in brain parenchyma is surrounded by perivascular macrophages.

rise to cells bearing longer, thinner, and branched processes (Monier et al., 2006). In addition to their capacity to proliferate in situ in response to injury, morphologically microglia appear as a distinct class of MP. The normal phagocytic functions of blood macrophages are considerably downregulated in ramified microglia; hence they are occasionally referred to as resting microglia. In response to injury or upon activation, they show a typical graded response and differentiate into immunologically active cells with functional and morphologic plasticity. Chimeric animal models have been extensively used to determine the myeloid origin of CNS microglial (Hickey et al., 1992; Lassmann et al., 1993; Hickey and Williams, 1996).

9.2.1.3. DC

DC are unique antigen presenting cells (APC) in that these cells can initiate the primary immune response. Both lymphoid and myeloid precursors can give rise to DCs. Evidence for the myeloid ontogeny of DCs was obtained when myeloid-committed precursors gave rise to mature DCs in vivo under the influence of granulocyte monocyte-colony stimulating factor (GM-CSF). However, transfer of lymphoid precursor cells in an irradiated mouse can give rise to DCs in addition to other cells of the lymphoid lineage, indicating their differentiation through the lymphoid lineage (Ardavin et al., 2001; Ardavin, 2003). In vitro, both human monocyte subsets can form DC when exposed to interleukin (IL)-4 and GM-CSF (Wu et al., 2001). Recently, a third population has been identified on the basis of CD64 expression. These cells resemble DCs and also have monocyte features (Tacke and Randolph, 2006).

Antigen presentation is essential for the maintenance of antigen-specific T cell responses in the nervous system (Groux et al., 2004; Karman et al., 2004). How this occurs remains incompletely defined. Although it is now well accepted that DC are the most potent APC type responsible for any primary immune response and occur through a strong and sustained ability to activate naive T cells the role of these cells in CNS immunity is hotly contested. The reasons are numerous. First, the differential phenotypes of DCs make their functional characterization in the nervous system difficult. Second, DCs are

both capable of initiating the immune responses and interestingly, of peripheral tolerance. Third, DCs constitutively express major histocompatibility complex (MHC) class II molecules and although upregulation of these molecules in response to inflammatory stimuli differentiation of their role in health and disease is difficult. Fourth, DCs actively participate in the humoral immune response. CD11c as well as CD205 and MHC class II can tract DC but are not always exclusive. DCs serve as nature's adjuvants. DCs express the pattern-recognition receptors such as toll-like receptors (TLRs) and can strongly influence the quality and the robustness of the immune response. DC-based therapeutic vaccines and TLRs present attractive ways to harness the innate and adaptive immune response in combating neurodegenerative disease.

9.2.2. MP-Specific Markers and Cellular Heterogeneity

Macrophages express a variety of surface markers that can be broadly classified into families of receptors including adhesion molecules, chemokines, lectins, advanced glycation endproducts (AGE), lipoprotein enzymes, cytokines, and Fc and complement. MP show well-developed enzymes including, but not limited to, nonspecific esterase expressed on the plasma membrane, acid phosphatase, alpha-glucuronidase, lysozyme, and peroxidase. Many of these are used for localization, identification, and isolation of MP. Table 9.1 provides a comprehensive list of these molecules. Several of the markers that are used for identification and localization of macrophages are denoted with an asterisk. Among the receptor families, scavenger receptors, glycosylphosphatidylinositol (GPI)-anchored receptors such as CD14, integrins (complement receptor), immunoglobulin superfamily (FcR), chemokine receptors, NK-like-C-type lectin (Dectin-1), C-type lectin (DC-SIGN), and the TLRs are important for immune recognition by macrophages (Gordon and Taylor, 2005).

Peripheral blood monocytes also exhibit heterogeneity in size, granularity, and shape of the nucleus. In addition, two distinct subpopulations of monocytes exist in circulation on

TABLE 9.1. Surface markers for macrophages/microglial.

Chemokine Receptors
CCR1, CCR2, CCR3, CCR5, CCR8, CCR9, CXCR1, CXCR2, CXCR4, CX3CR1
Complement Receptors
C3b, C3d, C3bi, C1q
Cytokine Receptors
Interleukins 1, 2, 3, 4, 6, 7, 10, 13, 16, 17
Interferon α , β , γ
Colony stimulating factors
Fc Receptors

Fibronectin & Laminin Receptors
Mannose, fucose, galactose
Integrins (CFA-1, CR3, CR4, VLA-4)
Toll-like receptors (Pattern Recognition)
CD4, CD14, CD16, CD45, CD68, CD163, HLA-DR

the basis of CD14 expression. CD14, a part of the lipopolysaccharide (LPS) receptor, is a surface marker used commonly for identification of monocytes. Differential expression of CD14 and CD16-the Fc γ RIII can segregate peripheral monocytes into CD14^{hi}CD16⁻ and CD14⁺ CD16⁺ types of monocytes. The classic monocytes, CD14^{hi}CD16⁻ cells, express higher amounts of MHC Class II and Fc γ RII molecules. CD14⁺ CD16⁺ monocytes express the chemokine receptor CCR5, a highly relevant receptor in human immunodeficiency virus (HIV)-1-infection of macrophages, whereas the CD14^{hi}CD16⁻ express CCR2 (Gordon and Taylor, 2005).

Although most of the tissue macrophages arise from circulating monocytes, it has been shown that local proliferation of monocytes does contribute to this pool. DCs differ in the surface marker expression depending on their lineage. In mice, the two subsets express high levels of CD11c, MHC Class II, and the costimulatory molecules CD86 and CD40. The most commonly used marker to differentiate between the two DC populations is CD8 α expressed only on the lymphoid lineage and not on the myeloid lineage. In humans, CD14⁺ and CD11c⁺ monocytes and lineage-negative CD11c⁻ IL3Ra are the two precursor pools of DCs. The immunobiology of DCs, ontogeny and the different outcomes of the immune response as influenced by DCs are extensively reviewed by Banchereau et al. (2000).

9.2.3. Heterogeneity of CNS Macrophages and Microglia

The heterogeneity that is archetypal to the MP member prevails within the localized CNS environment. Microglia, perivascular macrophages, meningeal macrophages, and choroids plexus macrophages are some examples of the MP-originated cells in the brain. The classical microglial cells (Figure 9.1) are bone-marrow-derived, reside in the brain parenchyma, and exhibit an arborized or ramified morphology in the resting stage. Typically, microglia have a small soma and ramified processes. Although these cells harbor the ability to perform all macrophage functions, in homeostasis, these cells have severely downregulated most of these functions and appear to be resting brain macrophages. Perivascular macrophages (Figure 9.1) are those cells that line the blood vessels and do not migrate deep into the brain parenchyma. Meningeal macrophages and choroids-plexus macrophages describe the locations of these cells. Meninges, the membranes that surround the brain or choroids-plexus (the location of the blood and cerebrospinal fluid interface), have macrophages that comprise the CNS MP pool. Depending on the type of the microglial cell, the kinetics of its repopulation may be varied. For example, meningeal macrophages may be replaced by bone-marrow-derived monocytes rather rapidly, whereas perivascular and choroids-plexus microglia replacement is relatively slower.

Among the subpopulations of monocytes, CCR2⁺ Ly6C⁺ monocytes are defined as the inflammatory monocytes, which are recruited to the site of inflammatory injury. The responses of these “inflammatory” monocytes to different stimuli are

intriguing. Depending on the stimulus, these monocytes may assume phenotypes that appear to be distinct *in vitro*. However, the existence of such phenotype plasticity *in vivo*, its significance, and whether these phenotypes are overlapping or mutually exclusive *in vivo* is currently unclear.

9.2.4. Markers to Distinguish Microglia from Other Brain Macrophages

Indeed, one of the challenges in developing transgenic mouse models with microglia-specific expression is the lack of a unique promoter that will express only in the microglia population. Thus, most of the strategies that attempt to distinguish microglia from other brain macrophages are based on quantitative differences rather than qualitative parameters (Flaris et al., 1993). The most commonly used method for isolation of microglial cells has been to enrich the CD45^{low} population (parenchymal microglia) from the CD45^{hi} population of peripheral and other macrophages (Dick et al., 1995). For rat cells, ED2 is used as a unique marker for perivascular macrophages. Recently, the scavenger receptor, CD163 is proposed to be the human homolog of this protein however, additional evidence is needed to confirm this. In humans, monkeys, and mice, CD163 is expressed at high levels on all circulating monocytes and perivascular macrophages rather than parenchymal microglia in humans, monkeys, and mice (Kim et al., 2006). Specifically, the CD14⁺ CD16⁺ monocytes express high levels of CD163.

9.3. Macrophages and Microglia: Biology and Function

According to the dominant viewpoint of the scientific community, microglial cells first become present in CNS tissue during the embryonic and early postnatal phases of development (Barron, 1995; Kaur et al., 2001). During this time when the brain is dynamic and undergoing constant remodeling, microglia are believed to assist in the clearance of undesirable cells through apoptosis (Thomas, 1992; Polazzi and Contestabile, 2002). In the mature brain under physiological conditions, resting microglia adopt a ramified morphology and serve as resident immune cells with very slow turnover (Wierzbak-Bobrowicz et al., 1995; Tanaka et al., 1998). Thus, microglia could be viewed as the first line of the innate immune mechanism in the brain. Macrophages and microglia, both MP, arise from hematopoietic stem cells in the bone marrow as described above. After passing through the monoblast and promonocyte states of the monocyte stage, they enter the blood. Then, they enter tissues and increase in size, phagocytic activity, and lysosomal enzyme content and become macrophages. The morphology of macrophages varies among different tissues and between normal and pathological states, and not all macrophages can be identified by morphology alone. However, most macrophages are large cells with a round or indented nucleus, a well-developed Golgi apparatus, abundant

endocytotic vacuoles, lysosomes, phagolysosomes, and a plasma membrane covered with ruffles or microvilli. The functions of macrophages include nonspecific phagocytosis and pinocytosis, specific phagocytosis of opsonized microorganisms mediated by Fc receptors and complement receptors, killing of ingested microorganisms, digestion and presentation of antigens to T and B lymphocytes, and secretion of a large number of diverse products, including many enzymes (lysozyme, collagenases, elastase, and acid hydrolases), several complement components and coagulation factors, some prostaglandins and leukotrienes, and several regulatory molecules. In this section, we will review the basic functions of the macrophage as a part of the immune surveillance mechanism.

9.3.1. The Four R's of Immune Response

As the immune responses involving MP participate in host defense mechanisms both against invading organisms and against injury, they involve four major components that include: Recognition, Recruitment, Removal, and Resolution/Repair. Both innate and adaptive immunity is involved in the process of recognition. The pattern recognition concept for innate immunity has evolved into a well accepted scheme of how immune recognition by APC is carried out using so-called pathogen-associated molecular patterns (PAMPs) by a limited number of germline encoded APC pattern recognition receptors (PRRs). In contrast, the adaptive arm of immune recognition involves a large repertoire of specific T and B cell receptors against specific peptides, generated by somatic recombination. The recruitment process of the immune response is largely mediated by the process of chemotaxis via chemokines generated at the site of injury. The recruitment of immune cells at the site of injury involves slowing of the cells in circulation, rolling against the vessel wall, binding to the wall close to the site of injury, followed by transmigration into the damaged tissues. This process plays a critical role in infiltration of peripheral cells into the brain during neurodegenerative diseases. Once at the site of injury, MP undertake the process of removal, which involves phagocytosis and intracellular clearance of the foreign bodies, apoptotic cells, and pathogens. These are discussed in some detail below.

9.3.2. Phagocytosis and Intracellular Killing

The phrase “to phagocytose” literally means “to eat.” This is an important function of MP that is shared with neutrophils. Phagocytosis is a critical defense mechanism operational not only against a variety of invading microorganisms including bacteria, viruses, fungi, and protozoa but also in cleanup of debris in tissue microenvironment. The process of phagocytosis involves amoeboid movements of cellular pseudopodia from the approaching MP. Three predominant pathways including the Fc-receptor-mediated phagocytosis, complement receptor-mediated phagocytosis, and the mannose receptor-mediated phagocytosis exist (Aderem and Underhill, 1999). Ligation of these receptors to

their specific ligands leads to cytoskeletal rearrangements in the MP that facilitate internalization of the particles. The presence of opsonins, which are recognition molecules that bind to both the invading particle and the MP, facilitate this process. Most commonly, immunoglobulin G (IgG) molecules and complement fragments serve as opsonins. This microglial function is deficient in the brain parenchyma in neurodegenerative diseases such as Alzheimer's Disease (AD), where deposits of amyloid beta ($A\beta$) are inefficiently cleared by the brain MP leading to senile plaque burden. Once the particles are surrounded and engulfed inside the MP, the process of intracellular clearance begins. The production of intracellular reactive oxygen intermediates (ROIs) is an important contributor to clearance as well as other enzymes. Fc receptor-mediated phagocytosis results in the release of large amounts of oxygen and arachidonic acid metabolites. Another mechanism is considered to involve charge compensation across the phagocytic vacuole membrane. The pumping of electrons into the phagocytic vacuole creates a charge that needs to be compensated. During this charge replenishment, the environment inside the vacuole favors enzymatic activity and microbial clearance (Segal, 2005). Additionally, this process of clearance does not occur until the phagosome with the engulfed particles fuses with the lysosomes to form the secondary lysosome also referred to as the phagolysosome. As mentioned above, MP in tissues are relatively long-lived and do not turnover rapidly. The long life span of most tissue macrophages allows for sustained phagocytic and clearance abilities in the repopulated microenvironments.

9.3.3. Antigen Processing and Presentation

MP are adorned with a remarkable ability to ingest a foreign moiety, digest it partially and present the broken down peptides in the context of the MHC proteins to the T cells. This whole process of antigen processing and presentation has been extensively reviewed in several articles (Frei and Fontana, 1997; Watts, 1997; Perry, 1998; Banchereau et al., 2000). Both MHC Class I and II molecules are thus presenting the protein environment of the MP for T cell surveillance. A majority of the peptides derived from foreign proteins are usually presented in the context of MHC Class II molecules rather than MHC Class I. Antigen processing is in part affected by factors intrinsic to the endosomal compartment, including pH, protease levels, and reducing potential. Other factors, such as the presence and vicinity of invariant chains for MHC Class II binding, interactions of the antigen with other proteins and modulation of lysosomal enzymatic activities may also influence antigen presentation. In essence, effective antigen presentation is achieved with a good balance between release of epitopes and their destruction. In addition, MHC Class II expression is necessary but not sufficient for presentation to T cells as additional costimulatory molecules are required for successful antigen presentation. The readout system for antigen presentation process is a functional one. The success of antigen presentation is usually measured as a T cell proliferation

response. However, not all antigen presentation phenomena necessarily lead to proliferative responses and may be restricted to cytokine production without proliferation.

The brain presents a special case for MHC Class II-related antigen presentation since microglial cells, the largest of the brain MP population, do not express high levels of Class II. However, Class II expression on microglia is readily enhanced upon activation. Indeed, upregulation of MHC Class II or human leukocyte antigen (HLA)-DR is a sign of microglial activation and is commonly associated with CNS pathologies and with neural injury. Thus, undoubtedly for antigen presentation in the brain at homeostasis, the perivascular macrophages are more important as they constitutively express MHC Class II. A new paradigm for the role of microglial cells in early immune responses in the brain has emerged in the form of TLR activation and this will be discussed in the current opinion section below (Gordon, 2002).

9.3.4. Secretion of Immune Factors

The innate pro-inflammatory response of these cells is activated upon exposure to LPS, prostaglandin or other TLR ligands, leading to production of classical proinflammatory cytokines including tumor necrosis factor (TNF)- α . On the other hand, classical activation by interferon (IFN)- γ and LPS leads to production of TNF- α and also increased secretion of reactive oxygen species (ROS) and inducible nitric oxide synthase (iNOS).

Macrophages and all MP in general, are known to produce a plethora of immune factors that are secreted into the environment and can act in a paracrine and/or autocrine manner. The microenvironment affects timing, dosage, and the receptiveness of the target cells. Moreover, there are very few of these immune factors that are solely attributed to MP, and multiple other cell types express immune mediators. Nonetheless, several of these factors may work in concert with others and it is difficult to delineate individual versus combined effects. Thus, the varied biological effects of these factors are not mutually exclusive and thus the net effect of the response in the microenvironment may be unpredictable. Table 9.2 provides an overview of the major

secretory families of MP. Among the proinflammatory cytokine family, TNF- α and IL-1 have the most pleiotropic effects.

9.4. Microglia and Neurodegenerative Diseases

9.4.1. Overview

Microglia are very sensitive in detecting changes in their microenvironment and react promptly to any alteration. These cells become readily activated following injury, during a neurodegenerative process, or upon interacting with misfolded proteins or invading pathogens. (Nakajima and Kohsaka, 1998; Streit et al., 1999; Mrak and Griffin, 2005; Vilhardt, 2005). Upon activation, microglia quickly proliferate, become hypertrophic, and upregulate a variety of surface receptors, including CD11b and those involved in antigen presentation to T cells, that is, MHC Class I and II and costimulatory molecules. Activation of microglia also induces changes in their phenotype as resting ramified cells become amoeboid and retract their processes upon activation (Thomas, 1992; Gehrmann, 1996). These cells can interact with T cells, activate T cells, and produce cytokines for further boost of an immune response. Besides morphological changes and upregulation of surface receptors, activated microglia also produce a plethora of secreted factors such as growth factors, pro- and anti-inflammatory cytokines, ROS, nitric oxide (NO), and glutamate. As would be expected from the variety of factors produced, some can potentially promote neuronal survival whereas others exacerbate neuronal degeneration (Table 9.3). Microglial activation is incited not only by bacterial antigens and pro-inflammatory cytokines, but also by self-compounds that exceed physiological concentration or acquire an altered structure (e.g., aggregation). For example, A β peptides associated with senile plaques in AD induce activation of microglia (Sriram and Rodriguez, 1997; Rangon et al., 2003). A similar effect is obtained with a protein found in lewy bodies associated with Parkinson's disease (PD), α -synuclein (Iseki et al., 2000;

TABLE 9.2. Microglial/macrophage secretory factors.

Complement
C1, C2, C3, C4, C5
Cytokines
TNF α
IL1, IL6, IL-10, IL-12, IL-15
IFN- α , IFN- γ
TGF- β

Arachidonic Acid Metabolites
Prostaglandin E2, leukotrienes
Platelet activating factors
Reactive Oxygen Species
Nitric oxide, peroxynitrite, superoxide
Hydrogen peroxide

TABLE 9.3. Microglial factors that affect neuronal protection/destruction.

Molecule	Effect on neuronal survival
NGF	Neuroprotective
BDNF	Neuroprotective
NT-3	Neuroprotective
NT-4	Neuroprotective
TGF- β	Neuroprotective
IL-10	Neuroprotective
IGF-1	Neuroprotective
VEGF	Neuroprotective
NO	Neurodestructive
H ₂ O ₂	Neurodestructive
Glutamate	Neurodestructive
Superoxide	Neurodestructive
Hydroxyl radicals	Neurodestructive
Peroxyntirite	Neurodestructive

Kitamura et al., 2001; Zhang et al., 2005). Due to the rapid response of microglia to environmental changes and upregulation of its activation markers following injury and during most neurodegenerative conditions, activated microglia are often found in conjunction with damaged sites in postmortem human tissue and in animal models. Indeed, activated microglia were colocalized with neuritic plaques in the brain regions of AD patients (Benveniste et al., 2001; Hoozemans et al., 2001; Meda et al., 2001).

As microglial cells are of the hematopoietic lineage, they respond to bacterial antigens and acquire a phagocytic phenotype *in vitro*. Under such stimuli, microglia produce NO and glutamate. Thus, conditioned media obtained from activated microglia leads to some extent of neurotoxicity in cultured neurons. Based on these observations, activated microglia were suggested to be neurotoxic and their proximity to damaged neurons led to a theory for microglia-mediated neurodegeneration (Liu et al., 2002; Liu and Hong, 2003; Kadiu et al., 2005). However, while microglia can contribute to neurodegenerative processes through the release of a variety of neurotoxic compounds, it has been shown that microglia can also protect neurons from degeneration by secreting other compounds (Grunblatt et al., 2000; Liu et al., 2002; Morale et al., 2006). Therefore, it should be remembered that the inflammatory process leading to the injured or diseased nerve is not a process mediated by a single type of cell, but it is rather a complex process of cellular interactions. As such, a discovery of activated microglia in conjunction with injured tissue does not necessarily imply that these cells are a part of the pathology as they could also be a part of the physiological healing process.

9.4.2. Acute Injury

Acute injury initiates a process of secondary degeneration, where neurons that were undamaged by primary injury but located in close proximity to damaged neurons degenerate due to high levels of neurotoxic compounds in the environment (Yoles and Schwartz, 1998). Why does the microglial response following this type of injury attract so much scientific attention? The answer to this question is simple—microglia are the major class of cells that populate the site of injury. Astrocytes, the main nonneuronal cells in the CNS, leave injured tissue and create the glial scar, thus delineating the site of injury (Moalem et al., 1999; Butovsky et al., 2001). Therefore, in this model it appears that the cells that can provide trophic support to injured neurons are mainly microglia.

The microglial response to injury is very rapid and within several hours activated ED1 positive microglial cells can be clearly found in the injured sites (Moalem et al., 1999; Hauben et al., 2000; Butovsky et al., 2001). Activated microglia demonstrate features of specialized macrophages and acquire rod-like or “bushy” morphology as seen in the white matter or gray matter, respectively (Sorensen et al., 1996). Activated microglia engage in the same activity as most tissue macrophages including the killing of microorganisms, stimulation

of inflammation, presentation of antigens, and liquefying and phagocytosing nonviable tissue. In injury activated cells express higher levels of MHC Class I and II molecules and show upregulation of complement type 3 receptor (CR3) and lectin binding proteins (Nelson et al., 2002).

Since activated microglia are implicated in exacerbating brain diseases, the biochemical markers and pathways that are stimulated by microglia in injury have been extensively studied. Several recent evidences clearly demonstrate that microglial phenotype after injury could be either destructive or protective (Butovsky et al., 2001; Nelson et al., 2002; Butovsky et al., 2005). In response to various stimuli, microglial cells will produce different sets of dominant compounds that differentially affect the fate of neural tissue. The partial list of common compounds can be found in Table 9.3.

One of the factors that controls microglial phenotype and determines the effect on neuronal survival is the adaptive immune response evoked by injury, namely the CD4⁺ T cells. T cells control not only the phenotype but also the microglial population size. In immune deficient rodents, microglial activation following injury is attenuated. Similar results are obtained in rodents with malfunctioning T cells. Moreover, a controlled T cell response changes the profile of molecules predominantly released by microglial cells (Shaked et al., 2004). Microglia activated following injury or *in vitro* by bacteria-derived antigens, such as LPS express high levels of pro-inflammatory mediators and possess a phagocytic phenotype. Following interaction with T cells, fewer neurotoxic factors are produced by microglia whereas production of neuroprotective growth factors and anti-inflammatory molecules is increased. Moreover, activation of iNOS in injury-activated microglia is high but can be down regulated upon interaction with T cells. Likewise, release of glutamate, one of the major neurotoxic agents produced by microglia, is altered as a result of interaction with T cells. Microglia that were activated by T cells reverse the glutamate transporters, which results in buffering rather than a release of glutamate (Butovsky et al., 2005, 2006a; Shaked et al., 2005). In normal brain tissue, glutamate buffering is mediated by astrocytes. Due to the lack of astrocytes at the site of injury, the role that microglia take in glutamate clearance presumably affects neuronal survival significantly. Microglia in the injured CNS tissue can be viewed as local guardians. If these guardians fail to correctly read incoming stress signals, then they will not develop the phenotype needed to fight off the threat, or alternatively, in fighting it off, the price they pay (in terms of death of neighboring neurons) is likely to outweigh the benefit (Schwartz et al., 2003, 2006).

9.4.3. Multiple Sclerosis

The role of activated microglia in neuronal survival during inflammatory conditions has been extensively studied in the models of experimental allergic/autoimmune encephalomyelitis (EAE) and in the animal model of Multiple Sclerosis (MS) (Antel and Owens, 1999; Becher et al., 2000; Biernacki et al., 2005; Jack et al., 2005). A rapid recruitment of blood-borne monocytes, an

activation of resident microglia and perivascular macrophages and the recruitment of autoimmune T cells are among the most consistent changes observed in MS and EAE. The initial and subsequently developed neural lesions in MS are characterized by a T lymphocyte-dominated inflammatory response, although monocytes, macrophages, and B cells are also present. The large variety of symptoms commonly attributed to MS reflects the heterogeneity of the disease (Lassmann et al., 2001). Two main kinds of demyelinating processes, each with its specific pathology, may be seen (alone or in various combinations) in patients with MS. Macrophage-mediated demyelination demonstrates radial expansion of the lesions, which are composed of inflammatory infiltrates (T cells and macrophages). Activated macrophages and microglia are associated with myelin destruction, attributable in part to macrophage cytotoxicity caused, for example, by TNF- α or ROS (Probert et al., 2000). The second type of demyelination is antibody-mediated. The lesions are similar to those seen in macrophage-mediated demyelination, with evidence of immunoglobulins and activated complement at active sites of myelin destruction. The inflammation is T cell-mediated and is activated by macrophages/microglia, with complement-mediated lysis of antibody-targeted myelin. Similar lesions are found in animal models of EAE induced by active or passive immunization with epitopes of myelin oligodendrocyte glycoprotein (MOG). Additionally, T cells in combination with demyelinating anti-MOG antibodies (Linnington et al., 1988) induce this type of demyelination.

As cells of the innate immune system, microglia serve as sensors of events occurring within the inflamed CNS. APC properties of microglia allow infiltrating immune cells to accumulate in the CNS (Nelson et al., 2002). The presence of antigen specific T cells at the sites of inflammation allows for bidirectional feedback in the CNS; thus, microglial-T cell regulation will play a crucial role in the propagation and resolution of inflammatory lesions. Monocytes infiltrating along with the T cells represent an important source of tissue macrophages that, once present in the CNS parenchyma, can fulfill parallel functions to microglia. Soluble products derived from autoimmune Th1 cells upregulate expression of MHC Class II, costimulatory molecules (CD80/86), CD40, and the adhesion molecule CD54 (ICAM-1) on microglia. Coculture of naive T cells with macrophages/microglia modulated by activated Th1 cells has been shown to promote a Th1-type phenotype in the responding T cells. Th1 soluble products also enhance the production of chemokines and cytokines (CXCL10/IP10, TNF α , and IL-6) by microglia (Sorensen et al., 1999; Flugel et al., 2001).

The acute CNS inflammatory response in MS and in EAE is self-limited, which is a contributing factor to the functional recovery that follows most clinical relapses (Antel and Owens, 1999; Jack et al., 2005; Prat and Antel, 2005). Histopathologic analyses indicate that a significant proportion of the infiltrating T cells (more than 70%) undergo programmed cell death and are subject to phagocytosis by microglia and macrophages. The rate of phagocytosis of apoptotic lymphocytes by microglia significantly exceeds that of nonapoptotic cells.

Such phagocytosis down regulates the immune functions of microglia, as measured by the production of proinflammatory cytokines and T-cell priming/proliferation. The down regulation of APC functions in microglia after phagocytosis of cells programmed to die may represent an active mechanism to limit the inflammatory response that characterizes the acute MS lesion (Williams et al., 1994; Prat et al., 2001).

Microglia/macrophages are central components of the MS lesion throughout all phases of the disease course and they are armed with a battery of molecules capable of damaging cells. The acute MS lesion has been classically defined based on the presence of phagocytes ingesting myelin and of infiltrating lymphocytes. The chronic MS lesion, on the other hand, which is characteristic of the progressive phase of the disease, is dominated by the presence of activated microglia/macrophages without a prominent lymphocyte component. Myelin itself has been shown to bind and activate complement. Cross-linking of FcRs on microglia can induce an oxidative burst in these cells (Iribarren et al., 2002). The production of ROS after a phagocytic burst could represent an important source of toxic microglia-derived mediators in the CNS, particularly in combination with reactive nitrogen species, present on MS plaques due to upregulation of iNOS (Brosnan et al., 1994; Mitrovic et al., 1996; Gebicke-Haerter, 2001).

Recent studies attribute a novel role to microglia as both supporters and blockers of oligodendrocyte renewal from the endogenous neural progenitor cells (NPC) pool in the adult CNS (Butovsky et al., 2006a, b). The *in vitro* findings showed that microglia activated with IL-4, in part via production of Insulin-like growth factor (IGF)-I and down regulation of TNF- α , were remarkably potent in counteracting the impediment to oligodendrogenesis induced by high-dose IFN- γ . *In vivo*, IL-4-activated microglia supported oligodendrogenesis and clinical recovery in rodents in which severe inflammatory conditions are known to evoke clinical symptoms of transient or chronic EAE. Injection of IL-4 treated microglia into the CSF of animals with acute or chronic EAE caused an increase in the number of newly formed microglia. Most of the new microglia expressed MHC Class II and IGF-I (Butovsky et al., 2006a, b). Recent evidence supports the active participation of IGF-I in maintenance of the integrity and homeostasis of the CNS. This growth factor was shown, for example, to play an important role in the differentiation and survival of oligodendrocytes and to be beneficial in the treatment of EAE. It seems reasonable to assume that the IGF-I produced by IL-4-activated microglia is responsible, at least in part, for the shift to a Th2 phenotype and thus for the increased number of MHC Class II+ microglia expressing IGF-I. The increased oligodendrogenesis in mice correlated with a higher incidence of newly formed MHC Class II+ microglia (Butovsky et al., 2006a; Schwartz et al., 2006).

9.4.4. Alzheimer's Disease

Alzheimer's disease is accompanied by widespread loss of neurons and synapses in the brain. AD brains also show disruption

of the blood–brain barrier and general metabolic deficit. The neuropathology of AD is mediated, at least in part, by amyloid plaques and neurofibrillary tangles (Durany et al., 1999).

Microglia are key players in the pathology and repair of AD (Eikelenboom et al., 2002; Rogers et al., 2002; Streit, 2004; Kim and de Vellis, 2005). Several laboratories have provided evidence that microglia demonstrate an apparently increased state of activation with age, thus providing partial explanation for the fact that aged brains are more vulnerable to developing lesions, which are composed of activated microglia. AD plaques are composed of a basic unit—A β peptide. In animals models of AD, microglia are a major component of amyloid plaques (Aisen, 1996; Marx et al., 1998; Marx et al., 1999; Bornemann and Staufenbiel, 2000; Emmerling et al., 2000). However, the fact that plaques can form in different ways may explain why some plaque types (dense-cored) are associated with microglial cells while others (diffuse) are mostly not. Beside A β , amyloid plaques contain many other substances such as lysosomal enzymes, cellular DNA, AGE etc., which are known to be sufficient to activate microglia. The hypothesis that microglia potentiate the toxicity of A β peptide is most directly substantiated by the physical proximity between amyloid fibrils and microglia (Streit, 2004; Streit et al., 2005).

According to the neuroinflammation theory of AD, the key pathological mechanism of AD is activation of the microglial cell. The neuroinflammation theory has originated from those studies that showed clustering of microglial cells within amyloid deposition in the human brains. These studies have been reinforced by numerous publications showing immunological activity of microglia. Proinflammatory molecules such as cytokines, complement components and MHC Class II receptors were detected in the AD brain in association with microglia. Studies on cultured microglia demonstrate that these cells can produce, in response to A β , a variety of neurotoxins (such as proteolytic enzymes, cytokines, complement proteins, ROS, N-methyl-D-aspartate (NMDA)-like toxins and reactive nitrogen intermediates). Several *in vitro* works proposed that A β may bind receptors for advanced glycation endproducts (RAGE) on microglia and thus stimulate intracellular signals leading to activation of transcription nuclear factor (NF)- κ B. Early evidence from epidemiological studies supported the neuroinflammatory hypothesis, suggesting a beneficial effect of the prolonged use of nonsteroidal anti-inflammatory drugs (NSAIDs) in reducing the risk of developing AD (Scali et al., 2000; Hoozemans et al., 2001; Eikelenboom and van Gool, 2004; Gasparini et al., 2005).

Recent results showed that exposure of microglia to A β , reminiscent of exposure to LPS, resulted in a cytotoxic microglial phenotype. Cytotoxicity was associated with upregulation of TNF- α . The cytotoxicity induced by LPS or by A β could be partly overcome by pretreatment of the microglia with IL-4 *in-vitro* (Butovsky et al., 2005). Other studies have shown that the induction of TNF- α expression in microglial cells by A β is dependent on the fibrillary state of the peptide; thus, for

example, A β (1–40) (which is nonfibrillar) does not induce TNF- α expression (Goodwin et al., 1995; Campbell et al., 2004; Rosenberg, 2005). Moreover, a recent study showed that the LPS receptor CD14, a key receptor for innate immunity, interacts with fibrils of Alzheimer's amyloid peptide. Neutralization of the receptor with anti-CD14 antibodies, or genetic deficiency of CD14, significantly reduces the microglial activation induced by these fibrils and attenuates the neurotoxic effect.

9.4.5. HIV-1-Associated Dementia

HIV-1 infects CD4+ cells of the immune system. Thus, in the brain, the primary targets of HIV-1 replication are the cells of the MP lineage. This includes microglia, perivascular macrophages, multinucleated giant cells formed post-viral infection and blood-monocyte-derived macrophages that infiltrate the brain during disease. The importance of activated microglia in the neuropathogenesis of HIV-1-associated dementia (HAD) cannot be understated. Indeed, virus-infected and/or immune activated MP secrete a variety of neurotoxic factors that affect neural function in HAD. Although monocytes and microglia remain the major cellular targets of HIV-1 in the brain, HIV-1 infection appears to be necessary, but not sufficient, to produce neurological disease (Nottet et al., 1996; Gendelman et al., 1997; Ghorpade, 1997). Thus, it is theorized that infected brain MP elicit disease through their secretory factors which induce both autocrine and paracrine cytokine production. These factors affect neural function through a complex circuitry of intercellular interactions between MP and various neural elements such as astrocytes, endothelial cells and neurons. The monocyte subset that expresses CD14 and CD16 is important in HIV-CNS disease (Fischer-Smith et al., 2001). This monocyte subset expands in the disease state and higher percentages of the CD14+ CD16+ monocytes correlate with HIV-1 disease progression. Similar to numbers of immune competent MP, activated microglia are known to produce a variety of cytokines that are upregulated in HAD. Pro-inflammatory cytokines include IL-1 β , TNF- α , and IL-6 among others.

9.4.6. Parkinson's Disease

Parkinson's disease is a common neurodegenerative disorder characterized clinically by resting tremor, slowness of movements, rigidity, and postural instability. The pathology of PD is associated with a dramatic loss of dopamine containing neurons in the substantia nigra pars compacta (SNpc) and their termini within the striatum, resulting in subsequent loss of striatal dopamine (Vila et al., 2001; Barcia et al., 2003). The detection of elevated levels of pro-inflammatory cytokines and evidence of oxidative stress-mediated damage in postmortem PD brains led to the notion of microglial involvement in the degenerative process. Indeed, a consistent pathological feature of the disease is the chronic activation

of microglial cells around degenerating neurons. With the exception of rare familial forms, the majority of PD cases are sporadic. Some epidemiological studies indicate a correlation between early-life brain injury and late development of PD, suggesting that inflammation in the brain, and specifically microglial activation plays a crucial role in the pathogenesis of the disorder, at least in its early stage. Additional evidence to support the notion of inflammatory processes in the brain as a pre-conditioning factor for development of neurodegenerative disorders, such as PD, is that people exposed to certain viruses or other infectious agents have an increased probability to develop PD or Parkinsonian-like syndromes (McGeer and McGeer, 1997; Vila et al., 2001; Teismann and Schulz, 2004; Hald and Lotharius, 2005; Nagatsu and Sawada, 2005).

Interestingly, the SN is an area extremely rich in microglia. As discussed above, microglia may serve as a source of ROS. Dopaminergic neurons in the SN are known to have a reduced antioxidant capacity, evidenced by a reduced level of the intracellular thiols, rendering them uniquely vulnerable to a variety of oxidative insults (Mirza et al., 2000; Koutsilieri et al., 2002; Hald and Lotharius, 2005). Therefore, it is reasonable to suggest that activation of microglia as a result of brain injury or infectious agent may serve as a risk factor and may trigger a cascade of events culminating in a massive death of dopaminergic neurons. There are several compounds that selectively damage dopaminergic neurons through microglial activation, such as rotenone (Gao et al., 2003), diesel exhaust particles (Block et al., 2004), and A β (Qin et al., 2002). Most of these toxins have a dual mode: they damage dopaminergic neurons via microglial activation at low concentrations, whereas at high concentrations, they induce a direct neuronal death. LPS, on the other hand, is toxic to dopaminergic neurons only via activation of microglia, and not directly. It should be kept in mind that the phagocytic phenotype of microglia induced by infectious agents and other compounds results in production of ROS, among other neurotoxic factors (listed in Table 9.3); thus, their neurodestructive effect is not restricted to dopaminergic neurons. Due only to the unique susceptibility of dopaminergic neurons to oxidative stress is the microglial neurotoxic effect so robust on these neurons.

Alpha-synuclein is a major component of lewy bodies, the morphological hallmark of PD. However, the pathophysiological role of this protein in degeneration of dopaminergic neurons is not understood. It was thought that alpha-synuclein exerts a direct damage on dopaminergic neurons; however, recent works demonstrated that microglia are capable of potentiating alpha-synuclein-induced neuronal degeneration. Alpha-synuclein leads to production of extra-cellular superoxide, increased production of ROS and induces morphological changes in microglia (Eells, 2003; Hishikawa et al., 2003). It should be mentioned, however, that microglia can also produce glial-derived neurotrophic factor (GDNF), a major factor shown to beneficially affect dopaminergic neurons (Connor, 2001; Chiang et al., 2005).

9.4.7. Glaucoma and Ocular Disorders

The origin of retinal microglia is controversial. Initial studies suggested neuroepithelial cells as an origin of microglia in the retina, whereas later studies provide evidence supporting a hematopoietic origin. Microglial precursors enter the developing retina via the ciliary margin prior to the organization of retinal vasculature and these cells differentiate into ramified parenchymal microglia. These cells express DC45, and MHC Class I and II molecules. In the developing rodent retina, most microglia are found at the vitreal surface at 12 days of gestation, and by 16 days of gestation, most microglial cells appear in a regular array across the retina. Microglia are largely confined to the ganglion cell layer and inner plexiform layer (Chen et al., 2002). While resting microglia are spread in different parts of the retina forming a network of cells with a potential immune effector function, their role in the normal retina is under-investigated. Microglia are considered to play a role in host defense against invading microorganisms upon injury and breakdown of retinal–blood barrier (Chen et al., 2002). Neurodegeneration activates microglial cells and facilitates their phagocytotic activity. Thus, these cells clean up cell debris from the damaged retina. However, an abnormal accumulation of activated microglia could also result in retinal dystrophy. Under inflammatory conditions in the eye, microglia serve as APCs and thus allow activation and proliferation of autoimmune T cells, which augment local inflammatory responses with potential destructive effects to adjacent neurons. Presentation of self-antigens by retinal microglial cells serves as a trigger for experimental autoimmune uveitis. Neuroprotective T cells, on the other hand, also require the presence of microglia at the site of injury to facilitate a neuroprotective response (Hauben et al., 2000; Butovsky et al., 2001; Kipnis et al., 2002). In glaucoma, for example, microglia function by clearing the debris and the deleterious breakdown products from degenerating retinal ganglion cells and their axons (Chen et al., 2002; Tezel and Wax, 2004). Boosting the T cell immune response further facilitates this beneficial effect and also leads to production of growth factors from microglia, which further facilitate neuroprotection (Schori et al., 2001; Bakalash et al., 2005). However, microglial cells also produce neurotoxic compounds and overactivation of microglia in the glaucomatous optic nerve head may be associated with immune-mediated neurodegeneration. In the retina, as with previously described neurodegenerative conditions, microglia serve a dual role in neuroprotection/neurotoxicity, which is determined by environmental factors and an adaptive immune response.

Retinal detachment associated with vitreoretinopathy is a complication of ocular trauma and vitreoretinal surgery. The mechanism leading to the detachment is not completely understood (Weller et al., 1991; McGillem and Dacheux, 1998; Valeria Canto Soler et al., 2002). Several studies suggest a role of MP, however; their origin was not

detected. Recently a distinct population of proliferating cells, presumably of microglial origin, was identified. These studies suggested that several soluble factors [e.g., transforming growth factor (TGF)- β] produced by invading macrophages and local activated microglia might underlie the mechanism for development of vitreoretinal pathology (Weller et al., 1990). Microglia may also be involved in the pathogenesis of age-related macular degeneration, which is associated with hypertrophy of retinal microglia as well as with diabetic retinopathy, since elevated numbers of microglia are also present (Chen et al., 2002; Caicedo et al., 2005; McGeer et al., 2005).

9.4.8. Neurogenesis

In the adult brain, the subgranular zone of the hippocampus and subventricular zone of lateral ventricles are the two neurogenic active zones that throughout adult life give rise to new neurons and glia cells from NPC. It was found that irradiation blocks differentiation of neural stem cells *in vivo* due to an inflammatory response caused by activated microglia. Blocking inflammation, elicited by either irradiation or injection of bacterial LPS in the rat brain using nonsteroid anti-inflammatory drugs prevented impairment of hippocampal neurogenesis (Monje et al., 2003). Similar impairment of hippocampal neurogenesis by injection of LPS was prevented by minocycline, a drug that blocks microglial activation (Ekdahl et al., 2003a; Ekdahl et al., 2003b). Thus, inflammatory mediators/cytokines released by microglia during an immune response to injury or disease strongly influence neurogenesis and neuronal function (Kempermann et al., 2003; Kempermann and Kronenberg, 2003). Proinflammatory cytokine IL-6 is the key factor involved in inhibition of neurogenesis *in vitro*; administration of an antibody to IL-6 selectively blocked the IL-6 effect and restored hippocampal neurogenesis *in vivo* (Monje et al., 2003).

Other studies have associated microglial activation with improved neurogenesis (Butovsky et al., 2006a; Ziv et al., 2006). Indeed, an enriched environment was shown to facilitate endogenous neurogenesis (Kempermann et al., 1998a, b). Examination of brains from animals kept in an enriched environment demonstrated activated microglial cells located in close proximity to hippocampal NPC. These microglia expressed MHC Class II molecules and also showed immunoreactivity to IGF-1 (Ziv et al., 2006), a major factor facilitating neurogenesis. Interestingly, these microglial cells were shown to interact with T cells (of yet unknown antigenic specificity). Depletion of T cells (using T cell deficient mice) abolished activation of microglial cells, which led to abrogation of the enriched-environment-induced facilitation of neurogenesis (Ziv et al., 2006). Similar results were obtained with minocycline, which blocks microglial activation. Similar to neurodegenerative conditions, microglia may play a dual role in neurogenesis, which is dictated by their phenotype determined in turn by environmental clues.

9.5. Future Perspectives

9.5.1. The Neuroimmune Synapse

Gap junctions in the brain have been predominantly studied in astrocytes. Gap junctions provide continuity in the cytoplasm of neighboring cells. Such gap junctions provide astrocytes with cellular transfer mechanisms for small molecules and secondary messengers. Although classically microglia were not considered to be gap-junction coupled, recent evidence suggests that under certain conditions, such as in injury, connexin (Cx) proteins are upregulated in microglial cells and may provide cell-to-cell continuity and communication in the areas of injury. Gap junctions consist of hemichannels contributed by cells juxtaposed to each other. The Cx family of proteins is involved in the formation of gap junctions. Microglia have been shown to express both Cx43 and Cx36, members of the Cx family of proteins and these observations, have implications in the neural cell network in inflammation and injury (Eugenin et al., 2001; Takeuchi et al., 2006).

9.5.2. TLRs Signaling in Macrophages and Microglia

TLRs are some of the recently recognized PRRs important in the early responses to pathogens. The pattern recognition concept was originally proposed by Janeway (Medzhitov and Janeway, 2000). Indeed, in microglial cells, TLRs are presumed to be key sensors of infection and initiate the innate immune responses. TLR members are identified on the basis of the molecular patterns and ligands they recognize. Lipid structures are recognized by TLR2 whereas LPS is recognized by TLR4. Viral and bacterial nucleic acids are recognized by TLR3, 7, 8, and 9, whereas dsRNA is recognized by TLR3. The signal transduction of activated-TLRs is classified into two major pathways. One pathway involves the activation of NF- κ B, which is a master switch for production of a variety of cytokines and effector molecules. The alternate activation pathway involves activation of microtubule-associated protein (MAP) kinase p38 and cJun NH2 terminal kinase (JNK). Most TLR (except for TLR3) signaling involves activation of a novel protein kinase IL-1 receptor associated protein kinase (IRAK) -1 and -4. The current discussion in the literature pertains to the mechanisms of TLR signaling during microglial responses to injury, and the potential of microglial TLRs to serve as rapid sensors and initiate innate immunity in the brain (Lee and Lee, 2002; O'Neill, 2006).

9.5.3. DC-Based Vaccines

The immune system thus applies both the innate and the adaptive immune responses as combined host defense mechanisms that operate in the periphery and in tissues including the brain. The main feature of adaptive immunity is its elasticity in generating diverse and yet specific immune responses.

However, the immune system is almost blind to all antigens that are provided in a soluble form; therefore, the use of adjuvants has a dramatic immune-stimulating effect. DC, the most powerful antigen-presenting cells, are capable of capturing, processing, and presenting antigens to T- and B-cells. This permits DC the capability for breaking self-tolerance. DC can stimulate cytotoxic T-lymphocytes to clear tumor or virus-infected cells. Vaccination with DCs can also affect clearance of tumors without eliciting autoimmunity (Zhang et al. 2007). They may also induce neuroprotective adaptive immune activities for models of neurodegenerative diseases (Schwartz et al., 2006).

Summary

Macrophages, microglia, and DC are the primary cell elements involved in the clearance and inactivation of microbial pathogens, in immune surveillance, and in homeostatic functions in all body tissues including the nervous system. Paradoxically, during disease these cells compromise are principal mediators of brain injury mediated through secretion of a variety of inflammatory neurotoxic factors and through precipitating adaptive immune responses. Modulation of macrophage and dendritic cell function mediated through environmental cues, microbial pathogens, or disordered protein structure or regulation leads to a wide range of pathological outcomes. The net result of a complex series of autocrine and paracrine amplification of immunoregulatory factors leads to intracellular events in neighboring neurons and glia that affect disease. Importantly, such events can now be controlled by immune intervention strategies that can prevent or slow neural tissue damage. Taming the function outcomes of macrophage and microglial activation is a frontier for research for neuroimmune pharmacology.

Review Questions/Problems

True/False

1. Microglia are solely neuroprotective cell.
2. Microglia are solely neurodestructive cells.
3. Microglial activation is always associated with impaired neurogenesis.
4. Microglia are not found in the retina but only in the optic nerve.
5. Retinal detachment associated with vitreoretinopathy as a result of complication of ocular trauma is mediated solely by microglia.
6. Microglia could be a source of IGF-1 in the brain.
7. Microglia can clear amyloid plaques, but not very efficiently.

8. Th1 soluble products enhance the production of chemokines and cytokines (CXCL10/IP10, TNF, and IL-6) by microglia.
9. T cells in combination with anti-MOG antibodies induce demyelination.
10. Astrocytes are the major cells of interest in the mechanically injured CNS.
11. Which of the following describe the shared functions of mononuclear phagocytes?
 - a. Phagocytosis
 - b. Intracellular killing of microbes and elimination of tissue debris
 - c. Secretion of bioactive factors
 - d. Antigen presentation
 - e. All of the above
12. Mononuclear phagocytes are a family of terminally differentiated cells with shared innate immune functions and include all of the following with the exception of?
 - a. Monocytes
 - b. Macrophages
 - c. Dendritic Cells
 - d. Histiocytes
 - e. CD4+ T lymphocytes
 - f. Microglia
13. The ontogeny of tissue macrophages includes the following in order of development?
 - a. Monoblasts to promonocytes to monocytes to tissue macrophages
 - b. Promonocytes to monoblasts to monocytes to tissue macrophages
 - c. Monoblasts to monocytes to histiocytes to Kupffer cells
 - d. Monocytes to promonocytes to tissue macrophages
14. All are histological features of monocytes and macrophages except?
 - a. Large, irregularly shaped cells with a kidney-shaped or round nucleus.
 - b. Ample cytoplasm in contrast to lymphocytes
 - c. Smooth surface
 - d. Differentiated cells commonly bear microvilli that are visualized with localization of vimentin
 - e. After activation cells revert to an activated state and appear amoeboid in nature
15. Macrophages express a number of surface markers that can be classified broadly into family of receptors that include all of the following except?
 - a. Adhesion molecules
 - b. Chemokines

- c. Lectins
- d. Advanced glycation endproducts
- e. TCR

16. Describe the neuroinflammatory theory of Alzheimer's disease

17. How can microglial responses be modulated during neurodegenerative conditions?

18. Is there a dual role of microglia in health and disease? How does this occur?

10.1. Introduction

The major function of the nervous system is to rapidly transfer and integrate information with a view to organizing the diverse functions of multicellular organisms. Our present understanding as to how nerve cells communicate originates with studies in the nineteenth century on the anatomy of the nervous system. Work conducted by Camillo Golgi and Santiago Ramon y Cajal defined the fine structure of neurons for the first time. Golgi favored the idea that all the nerves in the nervous system existed as a sort of reticular net, rather than as separate entities. Cajal, in contrast, concluded that neurons were independent entities and that a minute gap existed between the ends of nerve fibers and other nerve cells or the muscles that they innervate. This gap was ultimately named a “synapse” by the great neurologist Sir Charles Sherrington in 1897, from the Greek meaning “to clasp”. Cajal also argued that neurotransmission was basically a unidirectional process, information being received by dendrites and being transmitted unidirectionally along axons. The actual existence of the synapse as a structure was not confirmed until the development of the electron microscope in the 1950s. Around this time a fierce debate took place between two opposing sets of scientists (Valenstein, 2005). One set, primarily electrophysiologists, held the view that information was transmitted between nerves and between nerves and muscles by purely electrical processes. The other group, primarily pharmacologists, suggested that chemical messenger molecules were released by the presynaptic nerve and carried the information across the synapse. The nature of the chemicals that constitute neurotransmitters was gradually revealed by the work of several important investigators who characterized the effects of different substances that mimicked or blocked the actions of neurotransmitters on fast skeletal muscles and in the autonomic

nervous system. This finally culminated in the demonstration by Otto Loewi in 1921 that the vagus nerve secreted a chemical (“Vagusstoff”) that mediated the slowing effect of vagal stimulation on the heart. This substance turned out to be acetylcholine.

The term glia, or rather neuroglia (nerve glue), was first introduced by Virchow in 1859 who conceived of these cells as being neutral elements concerned in holding the nervous system together and playing a supportive role. Further studies by Ramon y Cajal and his colleagues divided glia into astrocytes, oligodendrocytes and microglia. We now know that glial cells are far from inactive support systems and are engaged in diverse dynamic interactions with nerve cells. Nissl suggested that microglia had the capacity for migration and phagocytosis and this has indeed proved to be the case. As opposed to other major cell types in the brain, the microglia are of mesenchymal origin and can generally be thought of as resident cells with macrophage like properties. Signaling between neurons and glia is involved in dynamically integrating the functions of the nervous system in health and disease. In general, signaling in the nervous system requires us to understand the properties of the different types of neurotransmitters, how they engage receptors and how this impacts the electrical and other properties of neurons and glial cells.

10.2. Electrogenesis and the Action Potential

10.2.1. The Resting Membrane Potential

The most common molecules in the body are water and inorganic molecules such as sodium, potassium and chloride ions. A feature that is common among all living cells is that the concentrations of these ions are different in the extracellular and intracellular compartments. The extracellular fluid is high in sodium (Na^+) and chloride (Cl^-) ions, but low in potassium (K^+) ions (Figure 10.1). In contrast, the intracellular solution is

FIGURE 10.1. Composition of major ions in the intracellular and extracellular compartments.

low in Na⁺ and Cl⁻, but high in K⁺. This difference is maintained and regulated by control mechanisms residing in the plasma membrane of the cell, a phospholipid bilayer with protein molecules inserted into it. The plasma membrane acts as a selectively permeable barrier permitting some molecules to cross while excluding others. When a pathway or “channel” for the movement of these charged molecules opens up across the plasma membrane, a phenomenon known as “gating”, the net movement of ions is governed not only by their concentration gradients, but also by the electrical potential difference across the plasma membrane. As we shall discuss below, neurons express proteins in their plasma membranes that act as channels allowing the selective permeability of different ions.

How does an electrical potential come into this picture? The movement of ions through selective pores in the membrane gives rise to a charge separation across the phospholipid bilayer, essentially giving rise to a “capacitor” and a potential difference across the membrane. It takes the movement of only a very small number of charges to give rise to a substantial membrane potential difference across the membrane. As a result, ions that are propelled down their concentration gradient encounter the electrical force that opposes their movement down this concentration gradient. Equilibrium for ion movement across the membrane is reached when the electrical force exactly balances the diffusional force arising from the concentration gradient. A relationship that describes the value of the electrical potential reaches at this equilibrium condition is given by the Nernst equation:

$$V = \frac{RT}{zF} \ln \left(\frac{[X]_{out}}{[X]_{in}} \right)$$

where V is the membrane voltage at equilibrium, $[X]_{out}$ and $[X]_{in}$ are the extracellular and intracellular concentrations of the ion being examined, R is the gas constant, T is the absolute

temperature, z is the valence of the ion, and F is Faraday’s constant. It is important to remember that the Nernst equation applies only to one ion at a time and only to ions that can cross the plasma membrane. For an ion in question, with a certain extracellular and intracellular concentration, the value of the electrical potential given by the Nernst equation is called the equilibrium potential.

For the typical ionic concentrations in mammalian cells (Figure 10.1), the equilibrium potentials for K⁺ and Na⁺ can be calculated from the Nernst equation to be -80 mV and $+57$ mV, respectively. If the plasma membrane is permeable only to K⁺ and no other ion, the membrane potential would be determined solely by the equilibrium potential for K⁺ and would be -80 mV. Real cells, however, are permeable to more than one ion at a time, and as a consequence, their resting membrane potential is influenced not only by the movements of K⁺, but also other ions, primarily Na⁺. For a typical cell that has a large K⁺ permeability at rest, if we increase the Na⁺ permeability to the membrane very slightly, the net effect would be to depolarize the membrane potential away from the equilibrium potential of K⁺ and toward the equilibrium potential of Na⁺. There is a struggle between Na⁺ on the one hand, tending to make the V_m equal to $+57$ mV, and K⁺ and Cl⁻ on the other hand, which push to make V_m equal to -80 mV. An equation that quantitatively relates these factors is the Goldman-Hodgkin-Katz equation (also referred to as the constant field equation because of the assumption made that the membrane field between the intra and extra-cellular compartment varies at a constant rate with distance). For a cell that is permeable to Na⁺, K⁺ and Cl⁻, this equation can be written as:

$$V_m = \frac{RT}{zF} \ln \left(\frac{p_K [K^+]_o + p_{Na} [Na^+]_o + p_{Cl} [Cl^-]_i}{p_K [K^+]_i + p_{Na} [Na^+]_i + p_{Cl} [Cl^-]_o} \right)$$

This equation is similar to the Nernst equation except that it simultaneously takes into account the contributions of all three permeant ions. It indicates that the membrane potential is governed by two factors: (1) the ionic concentrations, which determine the equilibrium potentials for the ions, and, (2) their relative permeabilities, which determine the relative importance of a particular ion in governing where V_m lies. For many cells, including most neurons and immune cells, this equation can be simplified: the chloride term can be dropped altogether because the contribution of chloride to the resting membrane potential is insignificant. In this case, the Goldman equation becomes:

$$V_m = \frac{RT}{zF} \ln \left(\frac{p_K [K^+]_o + p_{Na} [Na^+]_o}{p_K [K^+]_i + p_{Na} [Na^+]_i} \right)$$

Because it is easier to measure relative ion permeabilities than the absolute permeabilities, this equation can be rewritten in a slightly different form:

$$V_m = 58 \log \left(\frac{a[K^+]_o + [Na^+]_o}{a[K^+]_i + [Na^+]_i} \right)$$

where term $a = p_K/p_{Na}$ is the permeability of K^+ relative to Na^+ , and the term RT/F has been evaluated at room temperature and converted to log. In most cells at rest, the ratio a is about 50, resulting in a membrane potential of -71 mV for a cell with ionic composition as shown in Figure 10.1.

Because the steady-state membrane potential lies between the equilibrium potentials for Na^+ and K^+ , there is a constant movement of K^+ out from the cell and Na^+ into the cell. To ensure that this does not lead to a progressive decline in the concentration gradients across the membrane, all cells have a Na–K pump, which uses the hydrolyses of ATP to simultaneously pump K^+ into the cell and push Na^+ out. The constant fluxes of K^+ and Na^+ constitute electrical currents across the cell membrane, and at steady-state, these currents cancel each other out so that the net membrane current is zero.

10.2.2. The Action Potential

As noted above, the membrane potential is governed by the relative permeabilities for K^+ and Na^+ . If the K^+ permeability is greater than the Na^+ permeability, the membrane potential is closer to E_K . Conversely, if the Na^+ permeability far exceeds the K^+ permeability, the membrane potential should be closer to E_{Na} than E_K . In excitable cells such as neurons, ionic permeabilities are not fixed, but can be varied resulting in the occurrence of transient, dramatic changes in the membrane potential. It is these transient changes in the membrane potential brought about by changes in ionic permeabilities that underlies the action potential, a fundamental basic signal that sub-serves communication between all brain cells.

The typical profile of membrane potential changes during an action potential is illustrated in Figure 10.2. Following a small depolarization to a “threshold” value, there is a sudden, large jump in the membrane potential during which the potential transiently moves in the positive direction (referred to as a depolarization) and actually reverses in sign for a brief period. After peaking at a positive voltage, the membrane potential begins an equally rapid return toward its resting value, and transiently becomes more negative than its normal resting value. The last part of the action potential is a slow return to its resting value that often lasts several milliseconds. This is called the undershoot of the action potential. This basic electrical signal pattern is fundamental to neurons and is the basis of information transfer between neurons of the brain.

The key to understanding the origin of the action potential lies in the factors that influence the membrane potential of the cell as exemplified by the Goldman relationship. Recall that the membrane potential of the cell lies somewhere between E_K and E_{Na} . At rest, because the relative permeability of the membrane is much higher for K^+ than Na^+ , the

FIGURE 10.2. Various phases of the action potential. Once a depolarization reaches a certain threshold, the membrane potential moves rapidly in a regenerative manner toward E_{Na} . The opening of K^+ channels coupled with the inactivation of Na^+ channels causes the membrane potential to repolarize. The prolonged hyperpolarization (undershoot) results from slow closing of open K^+ channels following rapid repolarization.

point at which the membrane potential lies is closer to E_K . If the Na^+ permeability suddenly increases dramatically, then the membrane potential would correspondingly shift toward E_{Na} . For example, if p_K/p_{Na} changed from 50 at rest to 0.02, then the membrane potential would swing from -71 mV to 53 mV. After a brief delay, if the p_K/p_{Na} changed back to 50, the membrane potential would be expected to return to -71 mV. It is these transient changes in Na^+ permeability that are responsible for the swings in membrane potential from near E_K toward E_{Na} and back during the action potential.

10.2.3. The Sequence of Activation and Inactivation of Na^+ and K^+ Channels During an Action Potential

A dramatic increase in Na^+ permeability requires a dramatic increase in the number of channels that allow Na^+ to enter the cell. Thus, the resting p_{Na} is only a small fraction of what it could be because most membrane sodium channels are closed at rest. What stimulus causes the hidden Na^+ channels to reveal themselves? It turns out that the activation of these Na^+ channels is triggered by membrane depolarization. When V_m is at its usual resting levels around -70 mV, these Na^+ channels are closed and p_{Na} is low. However, depolarization causes the channels to open. Because the voltage-activated Na^+ channels respond to depolarization, the response of the membrane to depolarization is regenerative, and thus explosive (Figure 10.3). A small depolarization of the membrane opens Na^+ channels, which causes influx of Na^+ into the cell and additional depolarization, which in turn opens more Na^+ channels. This explains the all-or-none nature of the action potential: once it is triggered, it runs to completion.

FIGURE 10.3. Behavior of Na^+ channels and resulting changes in membrane potential during the rising phase of the action potential.

What causes V_m to return to its resting potential following the regenerative depolarization during the action potential? Two processes cause this: (1) the time-dependent inactivation of the depolarization induced increase in p_{Na} , and (2) a delayed increase in the p_{K} initiated by depolarization. A few milliseconds following the opening of voltage-activated Na^+ channels by depolarization, an “inactivation gate” is triggered which plugs the ion permeation pathway of Na^+ channels and shuts down channel activity, causing a dramatic decrease in p_{Na} . Almost at the same time as this is happening, depolarization-activated K^+ channels begin to open up, causing the p_{K} to dramatically increase. The closure of Na^+ channels and the opening of K^+ channels cause a dramatic increase in the $p_{\text{K}}/p_{\text{Na}}$ ratio, thereby shifting the balance strongly in favor of E_{K} . Therefore, the repolarizing phase of the action potential arises from the simultaneous decline in p_{Na} and an increase in p_{K} . In fact, the increase in p_{K} lasts for several milliseconds after the Na^+ channels close, causing the $p_{\text{K}}/p_{\text{Na}}$ ratio to be higher than at rest. This causes the V_m to be pushed closer to E_{K} , explaining the undershoot that follows fast repolarization.

How does the action potential propagate along the nerve fiber? This is easily explained by the basis for the generation of the action potential. As we have just seen, the stimulus for an action potential is a depolarization of sufficient strength to open large numbers of Na^+ channels to cause a regenerative membrane depolarization. Once such a depolarization occurs in one part of the cell, it brings neighboring regions above the threshold, setting up an action potential in that region. This in turn causes other neighboring regions to reach threshold and triggers the same gating schemes of Na^+ and K^+ channels to produce action potentials in those regions. The “inactivation” of Na^+ channels ensures that once an action potential has occurred in one region, it cannot immediately occur again in that region until Na^+ channels have recovered from inactivation. This causes the unidirectional movement of the action potential, away from the region that triggered the initial rise in membrane potential, and typically down the nerve fiber. This is the basis of the fundamental long-distance signal of the nervous system.

10.2.4. Transmission of Signals Between Neurons: Voltage-Activated Ca^{2+} Channels Mediate Neurotransmitter Release

Propagation of action potentials typically occurs from the somatic regions of neurons, through the axon and into the “terminals”—the tiny axon branches that terminate in synapses on neighboring neurons or end organs. As described below, invasion of the action potential into nerve terminals causes fusion of pre-packaged neurotransmitter-filled vesicles with the plasma membrane, releasing neurotransmitter across the synapse, and resulting in the activation of receptors on neighboring cells. What process couples the electrical action potential signal in the nerve terminal to the release of neurotransmitter? This is mediated by Ca^{2+} influx from the extracellular space into the nerve terminal through voltage-activated Ca^{2+} channels. Compared to Na^+ and K^+ , Ca^{2+} is present in much lower amounts in the extracellular space (1–2 mM) and was therefore ignored in the previous discussions of resting membrane potential and action potentials. However, as a chemical messenger inside the cell, Ca^{2+} mediates a variety of critical signaling functions. Nature has evolved such that the intracellular concentration of Ca^{2+} is of the order of only 100 nM. With the Ca^{2+} concentration in the extracellular space of 1–2 mM, this creates a 10,000-fold concentration gradient across the membrane. In addition, with these ionic concentrations, the Nernst equation indicates that the equilibrium potential for Ca^{2+} is also very positive. Therefore, near the resting potential, both the concentration and electrical gradients promote the movement of Ca^{2+} into the cell. When a conduit for Ca^{2+} entry, such as a voltage-activated Ca^{2+} channel opens up, Ca^{2+} rushes into the presynaptic intracellular space, elevating the local Ca^{2+} concentration, and resulting the fusion of neurotransmitter-filled vesicles through series of very rapid signal transduction events.

Voltage-activated Ca^{2+} channels are activated by membrane depolarization and represent a large family of related channels with a wide tissue distribution. They are found ubiquitously in neurons, muscles, and endocrine cells as well as in many epithelial and endothelial cells. In addition to neurotransmitter release, they mediate a variety of essential functions in the body including muscle contraction, insulin secretion, gene expression, modulation of signal transduction events and in excess can cause cell death.

10.2.5. Membrane Properties of Glial Cells

Intermingled with the neurons in the brain are a variety of other cell types. The most common of these “satellite” cells are glial cells. These make up virtually about one half of the total volume of the brain and exist in several forms such as astrocytes, oligodendrocytes, and Schwann cells. Membrane properties of glial cells exhibit fundamental differences from neurons, the chief difference being their passive nature. Unlike neurons, most glial cells are not excitable and do not fire action potentials. Membrane potential measurements of

glia indicate a relatively negative resting membrane potential—around -90 mV in contrast to -70 mV for most neuronal cells. This arises from the fact that, in contrast to neurons, the membranes of glia such as astrocytes and oligodendrocytes are permeable almost exclusively to K^+ .

Glial cells play several essential roles in neuronal function. Schwann cells form the well-studied myelin sheaths around large axons of peripheral nerves, enabling faster propagation of action potentials along nerve fibers by effectively increasing the membrane resistance of the fibers. The end-feet of astrocytic cells helps form the blood-brain barrier, which limits what substances cross over from the vasculature into the brain. Glial cells are also involved in guiding axons to their targets during neuronal development and during regeneration of nerve fibers after injury.

One particularly intriguing function of glial cells related to their unique membrane properties is the uptake of excess extracellular K^+ by astrocytes. When neurons fire repeatedly, K^+ accumulates in the extracellular space. Pumps and transporters in the neighboring astrocytes take up the excess K^+ and store it to protect neurons from the depolarization that could result from the increase in extracellular K^+ concentration. What happens next to the excess K^+ taken up? Astrocytes are connected to each other by electrical synapses—essentially cytoplasmic bridges between neighboring cells, forming sheets of physically connected cells. As a result, the K^+ taken up by astrocytes in one area is shuttled to neighboring astrocytes through the cytoplasmic bridges to draw it away from areas of high extracellular K^+ . It has been discovered that astrocytes lining membranes around the blood vessels have significantly higher K^+ channel density than the other cells of this network. The K^+ taken up by the astrocytic network is eventually extruded by so called “end-feet” specializations of high K^+ -channel density directly into the blood vessels. By this mechanism, the high K^+ permeability of astrocytes protects neurons from excess depolarization that could result from K^+ efflux into the extracellular space.

10.2.6. The Structure of Channel Proteins

A remarkable feature of ion channels is that once open, they promote the diffusion of ions down their concentration gradient often with extremely high selectivity and at extremely high rates (tens of millions of ions per second). What essential common structural elements confer ion channels with these properties? As might be expected, a first requirement is the existence of a pore region for passage of ions. The phospholipid bilayer is a hostile, low dielectric barrier to the passage of hydrophilic and charged ions. The amino acids of ion channel proteins provide a comfortable conducting hydrophilic pathway across the hydrophobic interior of the membrane. As a result, ion channels are necessarily transmembrane proteins with domains that span the membrane. Ion channels are usually constructed from the assembly of several subunits. A second requirement is the existence of a gating mechanism

that regulates the transport of ions across the pore. Channel gating is controlled by external factors (voltage, for voltage-activated channels, ligands for ligand-gated channels). Gating arises from the movements of protein domains that open or occlude the ion permeation pathway. Finally, the channel pores are often ion selective, discriminating between ions of varying sizes and charges to enable the passage of only a single ionic species.

How nature has evolved to solve these issues can be understood by exploring the structure of the K^+ channel. The crystal structure of a non-voltage gated, two transmembrane spanning K^+ -channel from the bacteria *Streptomyces lividans* (KcsA K^+ channel) has been solved to 2 Å resolution (Doyle et al., 1998; Zhou et al., 2001). Like its mammalian voltage-gated K^+ channel counterparts, the KcsA channel is a tetramer. Each subunit of this tetramer has only two membrane-spanning segments (instead of six for the mammalian channels), but it closely resembles the fifth and sixth transmembrane regions (S5 and S6) of the mammalian voltage-gated K^+ channels in its amino acid sequence. The two transmembrane segments in each subunit are α helices, with a peripheral and an inner helix (Figure 10.4D) that run almost in parallel through the membrane. The inner helix, which corresponds to S6 in the well-characterized *Shaker* potassium channel of *Drosophila* forms the lining of the inner part of the pore. The four helix pairs are like the support poles for an inverted teepee (with the top inside), widely separated near the outer membrane surface and converging toward a narrow zone near the inner cytoplasmic surface. The inner helices are tilted with respect to the membrane normal by about 25° and are slightly kinked with the wider part facing the outside of the cell allowing the structure to form the pore region near the extracellular surface of the membrane. This region contains the K^+ channel signature sequence, forming the selectivity filter, which discriminates between K^+ and Na^+ ions. Within the selectivity filter, the orientation of the amino acid side chains preclude their participation in ion coordination, leaving this function to the oxygen atoms of the main chain carbonyls. They form an oxygen ring coordinating dehydrated K^+ ions. Roughly in the middle of the membrane is a water-filled cavity, lined by hydrophobic amino acids, and at the bottom of the cavity is another constriction that is likely involved in channel gating (Yellen, 2002).

How does this structure explain the key issues of high ion selectivity, high ion throughput, and gating of K^+ channels? Selectivity for K^+ over Na^+ is explained by the binding of the carbonyl oxygens of the selectivity filter to K^+ ions. The spatial geometry of the selectivity filter and its energetics for ion binding is perfectly tuned for K^+ , the channel's natural ligand, but not for Na^+ and other ions (Yellen, 2001; Zhou et al., 2001). As a consequence, hydrated K^+ ions moving into the selectivity filter seamlessly lose their attached water molecules to form bonds with the selectivity filter. For Na^+ , the pore does not adjust to form good bonding, resulting in poor dehydration and migration of the water-attached Na^+

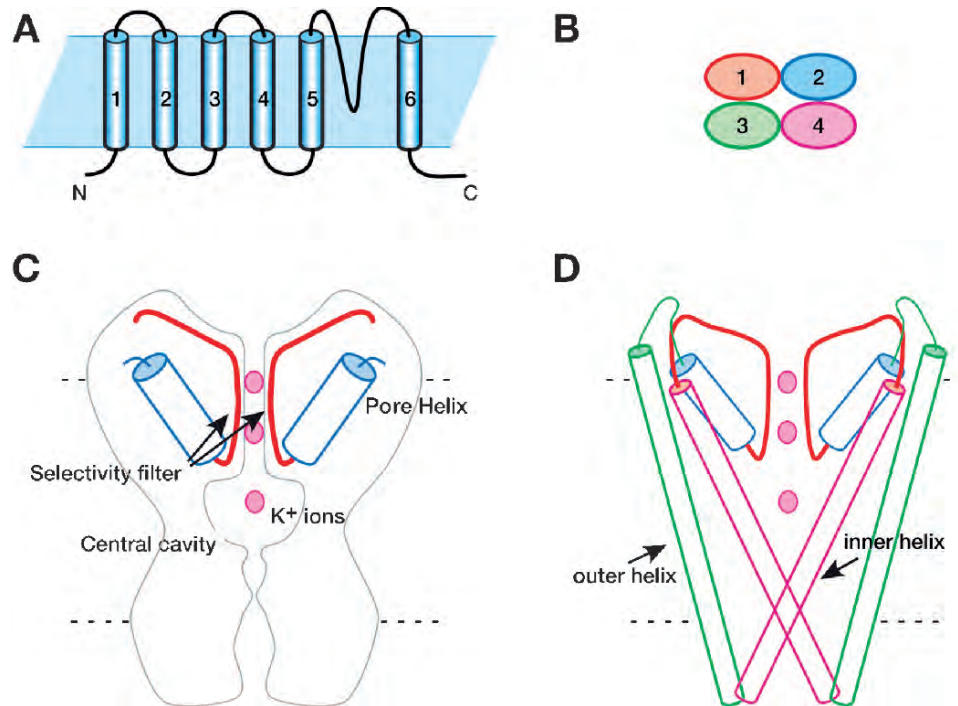

FIGURE 10.4 (A) Topology of a single subunit of a voltage-gated K⁺ channels. Hydrophathy studies predict the presence of 6 transmembrane α -helices. The sequence that spans the pore region is present between the S5 and S6 transmembrane helices. (B) Four identical copies of the K⁺ channel subunit shown in A assemble together to form the walls of the K⁺ channel. (C) Cross-section of an open K⁺ channel, based on the crystal structure of the bacterial K⁺ channel, KcsA. The selectivity filter, the wide intracellular cavity, and pore helix dipoles are highlighted. (D) A diagram derived from the high-resolution structure of the KcsA channel, showing the cross-over of the inner helices, corresponding to the S6 transmembrane segment of the mammalian K⁺ channels. The four inner helices produce a narrow opening that provides access to the water-filled cavity in the middle of the membrane protein. (adapted from Yellen, 2002).

into the selectivity filter. The tuning of the selectivity filter for K⁺ bonding also allows for its high throughput. New K⁺ ions entering the selectivity filter from the water-filled cavity expel one or more of the resident ions to the opposite side on the extracellular side and produce net transport. Because the water-filled cavity is hydrophobic, K⁺ ions in the cavity are less happy and impatient to get into the comfort zone of the selectivity filter, eliciting high throughput rate of ion movement. The structural basis for the phenomenon of gating is less well understood and currently the topic of intense discussion. It has been shown that the narrow constriction near the intracellular side created by the crossover of the two outer helices and lined by hostile hydrophobic residues, can close the ion permeation pathway and terminate the supply of K⁺ ions to the selectivity filter (del Camino and Yellen, 2001). This has been proposed to be the primary closing process. Additionally, by adjusting the tuning of K⁺-bonding and hence the rate of ion throughput, the selectivity filter itself has been proposed to underlie the opening/closing of the channel (Yellen, 2002).

The elucidation of the K⁺ channel pore structure has provided us with real insight and confirmation of abstract ideas on pores, filters, gates, and ion binding sites. Structures of other channels such as Na⁺ and Ca²⁺ channels await elucidation. Given the differences in ion selectivity and regulation

between K⁺ channels and these other channels, many differences are to be expected. However, fundamental similarities between these channels such as their pseudotetrameric subunit composition, voltage-dependent gating, and selectivity for specific ions suggest that the lessons gained from examining K⁺ channel structure are also likely to extend to these and other ion channel families (Hille, 2001).

10.3. Neurotransmitters and Neurotransmission

10.3.1. Classical Neurotransmitters

What types of molecules act as neurotransmitters and how does the process of neurotransmission proceed? Following the identification of acetylcholine (ACh) as a chemical neurotransmitter by Leowi, noradrenaline (or norepinephrine, NE) was identified through the work of Dale, Cannon and others as the neurotransmitter at many sympathetic neuroeffector junctions. Although ACh and NE are quite different from each other from the chemical point of view, they do share certain key features in terms of the way they act as neurotransmitters. These features are also shared by numerous other substances

that have subsequently been demonstrated to act as neurotransmitters, including other biogenic amines (e.g. dopamine and serotonin), amino acids (e.g. glutamate, GABA, and glycine) as well as many peptides (e.g. Substance P, NPY, CGRP, and the endorphins). Because of these shared features an informal consensus has gradually been reached setting out the “rules” for demonstrating that a substance acted as a neurotransmitter at a particular synapse. These rules are something like this:

- (1) The potential neurotransmitter substance should be localized in the presynaptic neuron together with the enzymatic machinery for its biosynthesis.
- (2) The substance should be released by stimulation of the presynaptic nerve. Because transmitter release has been shown to be dependent on the influx of Ca^{2+} ions through voltage dependent Ca^{2+} channels located in the nerve terminal (see above), evoked transmitter release should be Ca^{2+} dependent.
- (3) Drugs that block synaptic transmission at a particular synapse should also block the effects of the substance when it is directly applied to the postsynaptic cell.
- (4) A mechanism should exist (in addition to free diffusion) for terminating the action of the proposed neurotransmitter. Inhibition of this mechanism should prolong the time course of action of the proposed neurotransmitter.

It is clear that these criteria are fulfilled in the cases of ACh and NE acting as neurotransmitters at different synapses. Let us consider, for example, the effects of ACh at the synapse made by a motor neuron with fast skeletal muscle (“neuromuscular junction”).

- (1) ACh is found to be stored within the terminals of motor neurons. Detailed analysis has demonstrated that ACh is stored within small packages called synaptic vesicles that are concentrated around “active zones” on the presynaptic membrane. These active zones have been identified as specialized sites for neurotransmitter containing vesicle release. The enzyme for synthesizing ACh from choline and acetyl-CoA, choline acetyltransferase, is also found within the presynaptic terminal. Choline acetyltransferase is found in the cytoplasm. When ACh is synthesized it is pumped into synaptic vesicles by means of a specific carrier molecule located in the vesicle membrane. Once released, ACh subsequently diffuses across the synapse and activates nicotinic ACh receptors localized on the plasma membrane of the postsynaptic muscle cell producing depolarization of the muscle (see below).
- (2) Stimulation of the presynaptic nerve results in the release of ACh in a Ca dependent manner. Release of ACh can be demonstrated using a bioassay of the type originally employed by Loewi or more commonly nowadays by a direct chemical method.
- (3) Neurotransmission at these synapses can be inhibited by the drug d-tubocurarine, an antagonist of nicotinic ACh receptors. Direct application of ACh mimics the effects of nerve

stimulation, e.g. depolarization of the muscle and muscle contraction. D-tubocurarine also inhibits both of these effects.

- (4) The enzyme acetylcholinesterase (AChE) is localized at the synapse and degrades ACh released by the presynaptic nerve, thus limiting its actions. Inhibition of the effects of AChE (e.g. with a cholinesterase inhibitor such as physostigmine) prolongs the time course of action of ACh or of stimulation of the presynaptic nerve.

These observations are clearly consistent with the view that ACh acts as a chemical neurotransmitter at these synapses, indeed, they furnish the necessary “proof” of this proposed hypothesis.

Similarly, if we consider the effects of NE at noradrenergic synapses (Figure 10.5).

- (1) As with ACh, NE can be shown to be stored within vesicles localized to the presynaptic terminal. The enzymes responsible for NE biosynthesis are also found within the presynaptic terminal. The synthesis of NE is more complicated than the single step involved in ACh synthesis. In the case of NE an entire biosynthetic pathway exists with the initial step catalyzed by the enzyme tyrosine hydroxylase (TH) being rate limiting (Figure 10.5). TH activity can be precisely regulated at several levels (see legend to Figure 10.5). For example, it is subject to feedback inhibition by its products such as the catecholamines dopamine and NE. Following its biosynthesis, NE is pumped into synaptic vesicles using a specific pump localized in the vesicle membrane.
- (2) Stimulation of NE containing nerves is associated with the Ca^{2+} dependent release of NE.
- (3) Neurotransmission resulting from NE release can be blocked by a variety of drugs that block adrenergic receptors. These may be α or β blockers depending on the situation. Application of NE mimics the effects of nerve stimulation and these effects can also be inhibited by the same drugs. For example, vasodilation produced by stimulation of sympathetic innervation of blood vessels can be blocked by a blocker of α adrenergic receptors such as phentolamine.
- (4) Rather than being metabolized directly like ACh, the synaptic terminals of noradrenergic nerves express a high affinity uptake system for NE. Following its postsynaptic actions, NE is retaken up into the nerve terminals from which it was released via this high affinity uptake system and can be repackaged into synaptic vesicles. Drugs that block the high affinity presynaptic uptake system (e.g. cocaine and the tricyclic antidepressant amitriptyline) enhance the effects of presynaptic nerve stimulation or of exogenously applied NE.
- (5) The properties of classical neurotransmitters, as described for ACh and NE, can be applied with some variations to numerous other substances which have subsequently been determined to act as neurotransmitters. For example, in the case of amino acid transmitters such as GABA or glutamate, we would note that much of the released neurotransmitter is cleared from synapses by high affinity uptake into glial cells (astrocytes), in addition to nerve terminals. Peptide neurotransmitters, such as one of the endor-

FIGURE 10.5. (a) The enzyme choline acetyltransferase catalyzes the synthesis of acetylcholine (ACh) from Acetyl-CoA and choline. (b) Diagram illustrates the different phases of ACh synthesis, release and degradation by a cholinergic neuron. (c) Biosynthetic pathway for catecholamines such as norepinephrine (NE) in a noradrenergic neuron. Note that the rate of biosynthesis of a catecholamine transmitter can be regulated at three levels. First, feedback inhibition of the rate limiting enzyme tyrosine hydroxylase (TH) by NE, adrenaline (E) or dopamine (DA). Second, phosphorylation of TH by second messenger regulated kinases and finally, at the protein level of TH by transcriptional control of mRNA transcription. (d) Diagram illustrates the different phases of NE synthesis, release and uptake in a typical noradrenergic neuron.

phins, are synthesized in the soma of the neuron as inactive precursor molecules after which they are packaged into synaptic vesicles. These are then transported down the axon to the nerve terminal. The active peptide is cleaved from its precursor by proteases copackaged in the vesicle during its transport from the soma to the terminal. In response to nerve stimulation and Ca^{2+} influx the contents of the vesicle, including the peptide neurotransmitter are released.

As will be appreciated, in all of these cases neurotransmitters are ultimately packaged into synaptic vesicles. These synaptic vesicles are released from the terminal in response to a rise in intracellular Ca^{2+} . In most instances the source of this Ca^{2+} is the extracellular medium, and Ca^{2+} moves into the nerve terminal through voltage sensitive Ca^{2+} channels. A complex of proteins holds the vesicle in a “primed” state at presynaptic release sites, the active zones discussed above. Some of the proteins involved in this complex are provided by the vesicle (v-SNAREs) and

some by the presynaptic active zone (t-SNAREs). One or more proteins, in this complex senses the rise in Ca^{2+} and vesicle fusion and transmitter release ensues. The fact that neurotransmitters are stored within synaptic vesicles provides an anatomical basis for the properties of neurotransmitter release when recorded electrophysiologically. In particular, in electrophysiological recordings, transmitters are observed to be released in discrete packages or “quanta”. The evoked release of these quanta is dependent on Ca^{2+} influx via voltage dependent Ca^{2+} channels situated in close juxtaposition to the active zones, exactly where transmitter-containing vesicles are docked.

10.3.2. Novel Neurotransmitters

Although these traditional views of neurotransmitter function cover the properties of many neurotransmitters, it is now clear that numerous substances that act as neurotransmitters do not

fit easily into this description. Consider, for example, the endocannabinoids (Figure 10.6). Neurotransmitters in this class (e.g. anandamide and 2-arachidonoylglycerol, 2-AG) are lipid molecules derived from arachidonic acid which act as endogenous activators of the same receptors as the drug cannabis, the CB1 and CB2 cannabinoid receptors (Piomelli 2003). These transmitters show several features that differ from the above model. First, endocannabinoids are usually synthesized and released from the postsynaptic rather than the presynaptic cell. Secondly, although their synthesis is Ca^{2+} dependent, endocannabinoids are not stored in synaptic vesicles.

Following their synthesis endocannabinoids leave their cell of origin by a diffusion driven mechanism, rather than as discrete quanta. Endocannabinoids are frequently synthesized postsynaptically and then diffuse across the synapse to

produce effects on the presynaptic neuron. Thus, in this case neurotransmission may be viewed as occurring in the reverse direction! Furthermore, consider a molecule like NO, which is a gas and so also diffuses very easily. Here again its synthesis is dependent on an increase in Ca^{2+} . Once synthesized, however, NO can leave the cell by diffusion and enter target cells the same way. As in the case of endocannabinoids the information carried by NO may well travel backwards across the synapse, influencing presynaptic functions following its postsynaptic release. Both the endocannabinoids and NO are clearly neurotransmitters. They are responsible for the activity dependent transfer of information across synapses. However, their *modus operandi* is not at all traditional. Indeed, we could now list of whole host of molecules that can be released from neurons following electrical stimulation and which can then transfer information across synapses in the forward or back-

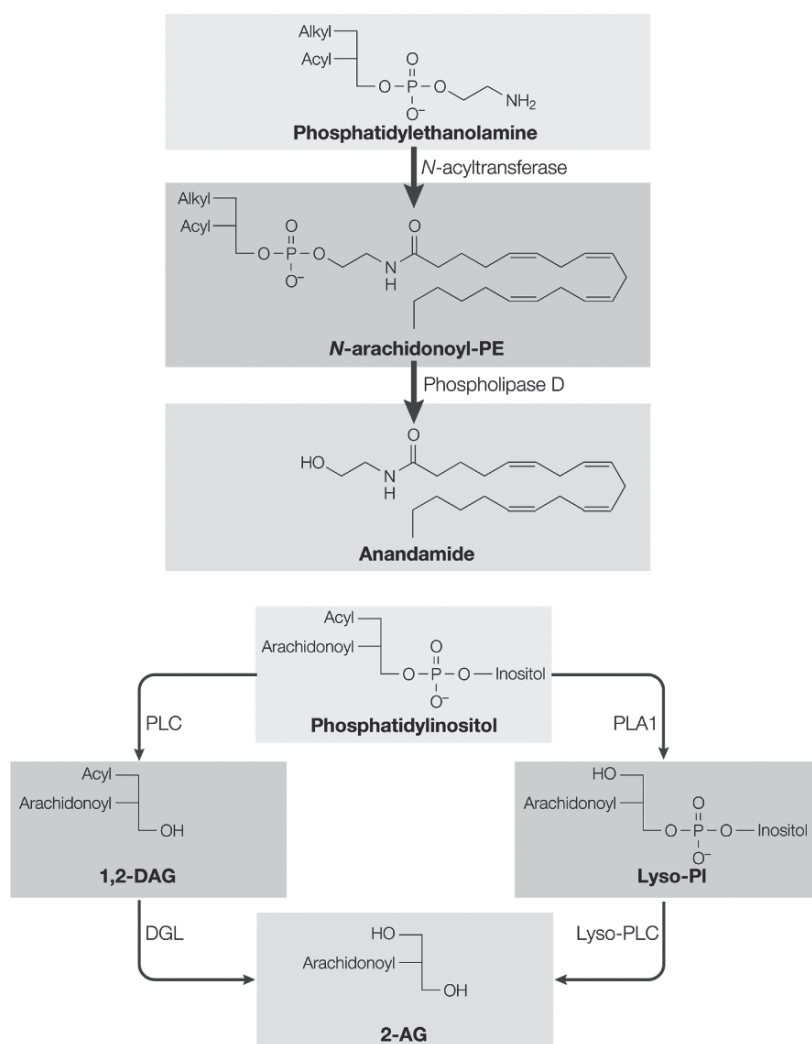

FIGURE 10.6. The biosynthesis of endocannabinoids. Biosynthetic pathways for the biosynthesis of the major endocannabinoids anandamide and 2-arachidonoylglycerol (2-AG). Note that the enzymes N-acyltransferase in anandamide biosynthesis. The biosynthesis of 2-AG can proceed via two different routes and is also dependent on an increase in Ca^{2+} . Figures reprinted from Piomelli (2003) with permission from Nature Publishing Group.

ward direction. These include a variety of growth factors and cytokines. Given the wide range of molecules that can apparently act as neurotransmitters, it is also true that information transfer across synapses can vary over a vast time scale ranging from very rapid electrical events taking a few milliseconds to much longer events taking hours/days and which involve changes in protein synthesis or gene transcription. As we shall now discuss, the type of information involved will depend on the receptor mechanism employed to decode the action of the neurotransmitter. Neurotransmitter receptors are expressed by neurons, glia and microglia and will be involved in decoding information transfer between all of these cell types.

10.4. Neurotransmitter Receptors

Once a neurotransmitter is released it will diffuse across the synaptic gap and interact with its target cell. The type of information “transmitted” to the target cell will depend both on the nature of the neurotransmitter and its receptor. As discussed above, this information transfer can be very rapid (perhaps a few milliseconds) or relatively slow (hundreds of milliseconds or even longer). Sometimes a single neurotransmitter can produce multiple types of signals if it can activate more than one type of receptor. Indeed, more than one receptor for a particular transmitter can be expressed simultaneously by the same target cell. If we consider our archetypal neurotransmitter ACh for example, its actions can be very rapid due to activation of the nicotinic class of ACh receptors, or its actions can be somewhat slower, due to activation of muscarinic ACh receptors. The effects of ACh typify the two major classes of neurotransmitter receptors—ligand gated ion channels (ionotropic receptors) that mediate rapid synaptic transmission, and G-protein coupled receptors (GPCRs, sometimes also called metabotropic receptors) that mediate slower synaptic transmission. Let us consider the structures of these receptors and how they function in neurotransmission.

10.4.1. Ligand-Gated Ion Channels (Ionotropic Receptors)

Ionotropic neurotransmitter receptors are a family of ligand gated ion channels. Normally, these channels exist in the cell membrane in a closed state. However, upon binding the appropriate neurotransmitter they open transiently and ions permeate the channel. This results in a redistribution of ions across the plasma membrane of the cell and a change in the membrane potential. This change in potential is the “signal” that can then be propagated by the target cell. A change in membrane potential of this type is a very rapid event taking only a few milliseconds.

In the case of the nicotinic ACh receptors at the neuromuscular junction, the structure of the receptor has been extensively studied and the structural basis for its properties is fairly well established (Figure 10.7). Nicotinic receptors are made up of a pentamer of subunits, which surround a central channel region that spans the membrane. X-ray crystallographic and electron

microscopic studies have revealed the overall structure of the receptor. The majority of its mass exists extracellularly in the form of a “vestibule” in which ions congregate. The receptor then enters the cell membrane as a channel or “pore” region, which narrows to highly restricted area in the middle of the membrane. Less of the mass of the receptor is found on the

FIGURE 10.7. The structure of nicotinic ACh receptors. Receptors are pentamers of 5 related subunits (a) which form a barrel like array in which the transmembrane region of each subunit (TM2) surrounds a central channel or pore region (b) electron micrographs have demonstrated that most of the mass of the channel is located extracellularly (c) The outside and inside of the channel pore region is surrounded by rings of negatively charged amino acids. These rings of negative charges will repel anions and attract cations resulting in a channel with cationic selectivity.

intracellular (cytoplasmic) side of the membrane. Intracellularly, receptors such as nicotinic receptors are often seen to be associated with cytoskeletal proteins that serve to localize them to the appropriate portion of the cell membrane, particularly opposite active vesicle release zones in the presynaptic terminal. The 5 subunits that make up the nicotinic receptor are all related transmembrane glycoproteins with molecular weights of around 25 KDa. Each of the subunits is a transmembrane protein that crosses the membrane 4 times (transmembrane regions 1–4; TM1–4), so that their N and C termini are both extracellular. The five subunits are arranged like a barrel in which the central ion channel or pore is created by one TM2 region supplied by each subunit. The five subunits that make up the receptor consist of two α subunits, one β subunit, one γ subunit and either a δ or ϵ subunit. Although these are all proteins of closely related sequence, only the α subunits have binding sites for ACh. ACh molecules bind cooperatively to the receptor producing a conformational change and increasing the probability of channel opening or “gating.” When two ACh molecules bind there is a high probability of channel opening. Once open, the channel is permeable to cations, which permeate the pore region moving down their electrochemical gradients. As discussed above, at normal resting potentials Na moves into the cell and K moves out. The net result of this ionic flux is depolarization of the cell as the membrane potential moves toward the reversal potential of the nicotinic receptor channel—i.e. 0 mV. Sufficient depolarization of the postsynaptic cell will trigger an action potential. If receptors are exposed to ACh for longer periods of time they change conformation once again to a form a “desensitized” state, in which ACh remains bound to the receptor but the channel is closed. The selectivity of nicotinic receptors for cations over anions is engendered by an interesting structural motif. As can be seen in Figure 10.7, both the extra and intracellular regions of the receptor just outside the cell membrane are surrounded by a ring of amino acids with a net negative charge. Hence any cation will be attracted into the channel whereas any anion will be repelled. Nicotinic receptors in other parts of the nervous system, including the sympathetic ganglia and the brain, are also thought to be composed of pentameric arrays of subunits. These subunits are members of an extended gene family of nicotinic receptor subunits that can associate in multiple different combinations of α and β subunits (Gotti and Clementi, 2004). For example, in the brain many nicotinic receptors may exist as pentamers of the $\alpha 4\beta 2$ combination. Indeed, some receptors e.g. $\alpha 7$ exist as a homomeric array of the same subunits. The basic properties of all of these nicotinic receptors are the same but some of the details differ. For example, in addition to being permeable to Na^+ and K^+ , some receptors (e.g. $\alpha 7$ pentamers) are also highly permeable to Ca^{2+} . Given the importance of Ca^{2+} as an intracellular second messenger, this may have important signaling consequences.

The pentameric arrangement of subunits used to construct nicotinic receptors is also utilized to make up other types of

ligand gated ion channels including the GABA-A, glycine and 5-HT₃ receptors. Here again the subunits used are members of the same extended gene family of proteins as those that make up nicotinic receptors, and the basic structure of the receptor as well as its mechanism of action are similar. Interestingly, the GABA-A and glycine receptors are anion (chloride and bicarbonate) rather than cation permeable channels, a property based on the same structural motif that makes the nicotinic receptors cation selective. However, in this case the channels possess rings of positive rather than negative amino acids. GABA-A receptors are highly important as they mediate the rapid effects of GABA at most of the synapses in the brain. Furthermore, these receptors are also the targets for many pharmacologically significant substances including anxiolytic and hypnotic drugs. As in the case of nicotinic receptors the precise subunit composition and properties of GABA-A receptors vary throughout the neuraxis depending on the precise combination of subunits utilized. The ability to target drugs to these various subclasses or receptors allows for the production of agents with selective anxiolytic or hypnotic properties, for example.

Another important family of ligand gated ion channels is the receptors for the excitatory amino acid neurotransmitters such as glutamate and aspartate (Figure 10.8). These act as neurotransmitters at the vast majority of excitatory synapses in the brain. These receptors are also multisubunit ion channel arrays, in this case consisting of tetramers of related subunits (Wollmuth and Sobolevsky, 2004). The proteins that make up these subunits are all related in structure but are quite different from those that make up the nicotinic and GABA-A receptor family.

In the case of glutamate receptors the basic structure of each subunit is a protein that crosses the membrane 3 times. The TM2 or P region, which again forms the pore of the channel, does not cross the membrane entirely and forms a loop like structure that folds back into the membrane. Indeed, the basic structure of this pore region bears similarities to that described above for K^+ channels. The overall structure of each subunit consists of a large N-terminal extracellular region attached to a transmembrane region that forms the channel. It is interesting to note that the large extracellular region is related in structure to ancient bacterial periplasmic amino acid binding proteins. Similar extracellular motifs also make up the N-terminal of metabotropic glutamate receptors, although in this case they are attached to a 7 transmembrane core rather than an ion channel motif (Jingami et al., 2003 Figure 10.8). In the case of the ionotropic glutamate receptors, binding of glutamate to the “clam shell” region in the extracellular portion of the receptor closes the clamshell, initiating a conformational change that eventually results in channel gating. There are basically 3 types of glutamate receptors, named for archetypal agonists that activate each class—these being AMPA, kainate and NMDA receptors. The subunits that make up these receptors (GluR subunits) are all related and form an extended gene family. Although their basic structures

FIGURE 10.8. The structures of ionotropic and metabotropic glutamate receptors. (a) Family tree of related protein subunits that constitute different types of ionotropic glutamate receptors. (b) Typical domain structure of a glutamate receptor subunit. The extracellular regions show homologies to bacterial periplasmic binding proteins. (c) Structure of a metabotropic glutamate receptor. In this case the extracellular region also bears homology to a bacterial periplasmic binding protein, but this time it is attached to a 7-transmembrane G protein coupled receptor motif. Metabotropic glutamate receptors probably function as dimers or other higher order arrays.

and gating mechanisms are similar, there are some interesting details that distinguish each type. The AMPA receptors are made up of tetrameric arrays of the GluR 1–4 (or A–D) subunits. These receptors are basically cation selective channels that are relatively impermeable to Ca. However, it was demonstrated that the structure of the channel as coded in the genome was slightly different. The originally coded GluR2 subunit possessed a single glutamine residue in the TM2/P loop region. This is the region of the channel that makes up the cation permeable channel pore. In contrast to the sequence coded in the genome, the subunit normally found to exist in functional AMPA receptors expressed in cells has an arginine residue in exactly the same position. The triplet code for Gln is CAG. It was shown that neurons express a highly specific adenine deaminase that “edits” this triplet to produce C-Inosine-G, which is then read by the protein synthetic machinery as CGG or arginine. It was observed that Gln or Arg containing channels differed in their Ca²⁺ permeabilities, the extra positive charge associated with Arg repelling Ca²⁺ ions and making the channel relatively Ca²⁺ impermeable. It is possible, however, that in some cases editing of GluR2 may be incomplete or that some tetrameric AMPA receptors may not include an edited GluR2 subunit and are therefore Ca²⁺ permeable. Thus, a single base change produced by RNA editing can completely change an important property of these AMPA receptors, i.e. their permeability to Ca²⁺.

In the case of NMDA receptors Ca²⁺ permeability is also an important issue and is a key to understanding certain forms of glutamate mediated synaptic plasticity (see below). These properties of NMDA receptors can be readily observed through

a consideration of their electrophysiological properties (Figure 10.9). Let us compare the properties of AMPA and NMDA receptors. When recorded in physiological solutions, currents carried via AMPA receptors display current/voltage (I/V) relationships that strictly follow Ohm’s law. On the other hand the I/V relationships for NMDA receptors exhibit a region of “negative slope conductance” similar to that displayed by voltage dependent channels, such as voltage sensitive Na⁺ or Ca²⁺ channels (see above). An important discovery was that this behavior was not due to the intrinsic gating properties of the NMDA receptor protein itself. It was observed that if Mg²⁺ was removed from the physiological bathing solution in which the measurements were made, currents carried by NMDA receptors behaved in a strictly Ohmic manner just like the related AMPA receptors. Further investigations revealed that NMDA receptors can be blocked by Mg²⁺ at hyperpolarized membrane potentials. As the cell depolarizes the block by Mg²⁺ is relieved. This behavior means that glutamate will only activate an NMDA mediated current when the cell is relatively depolarized. This has important implications for the mechanisms underlying some types of synaptic plasticity (see below).

10.4.2. G-Protein-Coupled Receptors/GPCRs

In addition to ligand gated ion channels neurotransmitters often activate GPCRs. These receptors are all based on a structural motif in which the receptor protein crosses the membrane 7 times in a serpentine like manner so that that N-terminal is extracellular and the C-terminal is intracellular. This arrange-

FIGURE 10.9. Biophysical properties of the N-methyl-D-aspartic acid receptor. The current voltage (*i/v*) relationship measured in physiological solutions shows a region of “negative slope conductance” at hyperpolarized potentials. Little inward current is observed until the cell is substantially depolarized. However, when Mg^{2+} is removed from the bathing medium the *i/v* relationship follows Ohm’s law and is represented by a straight line. The reason for this behavior is that Mg^{2+} block NMDA receptors in a voltage dependent manner (see main text).

ment results in the formation of three intracellular loops between the different transmembrane regions of the protein. These loops can be used to transduce signals to the inside of the cell and, in particular, to heterotrimeric G-proteins. GPCRs constitute an extremely large gene family and include many variations on the same basic structural motif (Figure 10.10). However, in virtually every instance the mechanism of action is basically the same. Binding of the agonist produces a conformational change in the receptor that leads to activation of the G-protein. G-protein activation results in its dissociation into α or $\beta\gamma$ subunits—either of which can then mediate signal transduction within the cell. In the classical description of GPCR function the downstream signal is typically produced through the regulation of an enzyme like adenylate cyclase or phospholipase C. Activation of these enzymes produce second messenger molecule such as cAMP, diacylglycerol (DAG) or Ca^{2+} that then activate protein kinases or other effectors. For example, phosphorylation of ion channels by activated kinases changes their gating properties and so transduces the message to the level of electrical signaling. However, this classical model is only one of many possible alternatives. The subunits of the G-protein may bypass the kinase activation step and interact directly with the channel protein, resulting in direct channel gating. For example, direct interaction of G-protein $\beta\gamma$ subunits with K^+ channels or N-type Ca^{2+} channels can

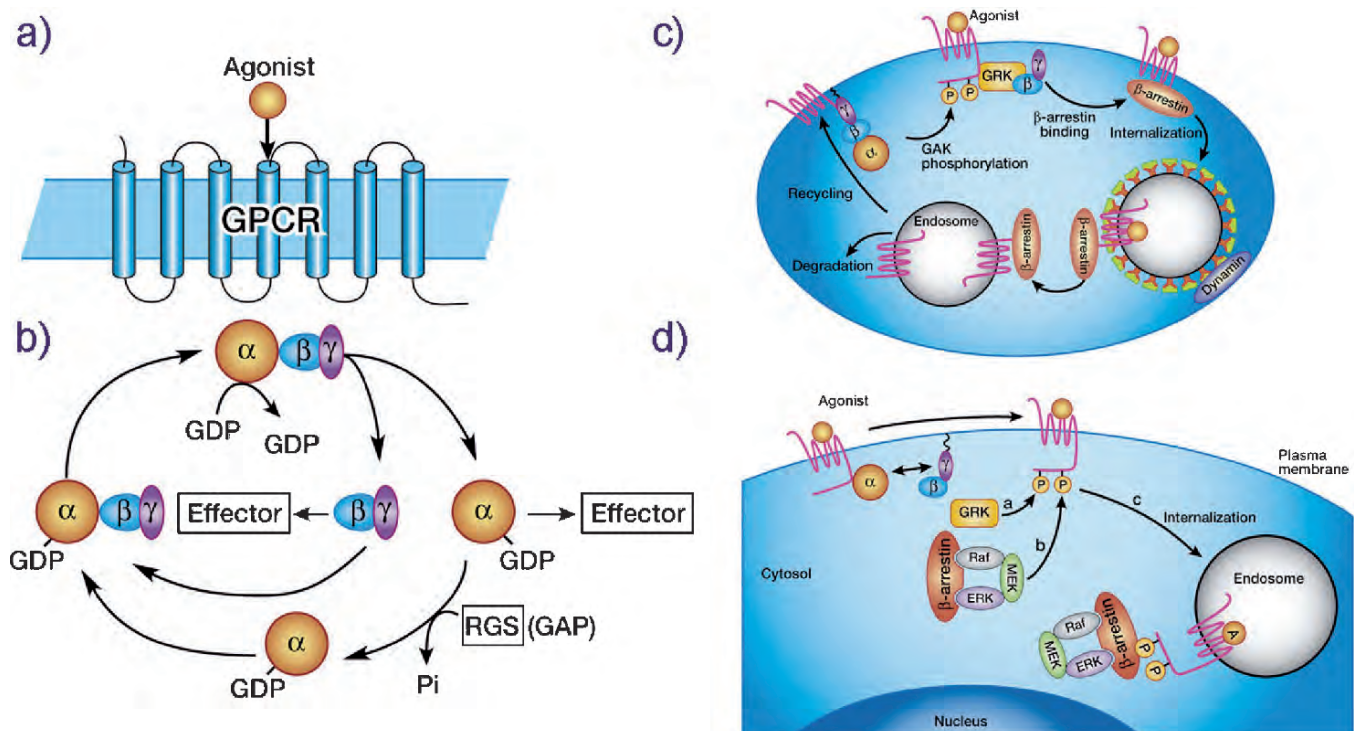

FIGURE 10.10. G-protein coupled receptor (GPCR) structure and function. (a) The basic 7-transmembrane structure of a GPCR is common to all members of the family. (b) The cycle of heterotrimeric G-protein activation. The cycle is initiated by stimulation of GTP/GDP exchange on the G-protein α subunit produced by an agonist induced conformational change in the GPCR. (c) Activation of a GPCR also produces interactions with proteins of the β -arrestin family that mediate uncoupling of the GPCR from its G-protein and receptor internalization. (d) Arrestins can also act as scaffold proteins that bring together members of the MAP kinase pathway and so activate MAP kinase signaling.

directly modulate channel function by activating K^+ channels or inhibiting N -channels. Such effects can directly modulate neurotransmitter release at nerve terminals. Although such a model is generally applicable to the activation of GPCRs, in the case of certain GPCRs that are important in the nervous system the basis for signal transduction is not entirely clear and may not even involve a traditional G-protein. Thus, for GPCRs of the frizzled or smoothened families, which are involved in the important Wnt and hedgehog signaling pathways, the precise mechanisms of signal transduction are not known and the role of G-proteins is unclear. Thus, as we shall discuss below, activation of a heterotrimeric G-protein may be only one way in which a GPCR can ultimately transduce information.

How does a GPCR normally work from the molecular point of view? In order to answer this question we should first consider how G-proteins produce their effects (Figure 10.10). For heterotrimeric G proteins the α -subunit has intrinsic GTPase activity. Normally GDP is bound to this subunit. In order to initiate a cycle of G-protein mediated signaling this GDP moiety must be replaced by a GTP molecule. Binding of GTP results in dissociation of the G-protein into α and β subunits and signaling ensues. Once the GTP has been hydrolyzed the heterotrimer reforms and signaling ceases. In order for these events to be carried out two proteins are important in addition to the G-protein. The first of these is a GEF or “guanyl nucleotide exchange factor”. This protein is responsible for stimulating the initial exchange of GTP for GDP. Because the intrinsic GTPase activity of most α -subunits is low a second protein called a GAP (GTPase activating protein) is required. This protein acts upon the GTP bound α -subunit to enhance its GTPase activity and so allow the cycle of G-protein mediated signaling to terminate. In this context the GPCR can be seen to act as a GEF. Under resting conditions the heterotrimeric G-protein is bound to the intracellular loops of the receptor. Binding of the agonist produces a conformational changes such that the receptor now stimulates exchange of GDP by GTP bound to the α -subunit and initiates signaling. Thus, the GPCR is an agonist activated GEF. The arrangement of GPCR and heterotrimeric G-protein is a special case of G-protein mediated signaling. In other cases “small” G-proteins such as Ras, which carry out numerous cellular signaling functions, are not heterotrimers but also function in GTP regulated manner. In this case other proteins have GEF like activity to promote guanyl nucleotide exchange.

Signaling mediated by GPCRs has been shown to be a very information rich event which is much more complex than initially supposed. In order to understand this we should consider the entire sequence of events that takes place when a GPCR is activated. Here again there are many variations on the basic theme, but it appears that there are other signaling pathways that are activated in addition to G-proteins. Binding of the agonist to the receptor initiates conformational changes in the intracellular C terminal region. This allows diverse residues in this region to be phosphorylated by kinases of the GRK (GPCR

kinase) family. Phosphorylation of these residues has numerous effects. First, the interaction of the receptor and G-protein is interrupted. Secondly, the phosphorylation of the GPCR allows it to interact with proteins of the β -arrestin family (Lefkowitz and Shenoy, 2005 and Figure 10.10). This interaction was initially shown to allow the GPCR to be relocated to a region of the membrane (coated pit) resulting in receptor endocytosis. When internalized into the cell in this way the receptor may be dephosphorylated and recycled back to the cell surface or else it can be degraded in the lysosomes. As will be obvious all of these actions will result in interference of the basic signaling functions of the receptor by uncoupling it from the G-protein and/or removing it from the surface. This acts as a negative feedback loop controlling the extent of GPCR signaling in the face of continuous receptor stimulation. However, it has subsequently been demonstrated that β -arrestin like molecules have a very large number of additional receptor related functions. For example, β -arrestins can act as scaffolding proteins for the intermediates of the MAP kinase signaling cascade. Thus, once activated by a GPCRs arrestins might bind MAP kinases allowing for their mutual phosphorylation and activation. The overall effect of this is to inhibit the initial signaling of the GPCR and to redirect it down the MAP kinase pathway. Indeed, it has been frequently observed that activation of a GPCR can produce activation of ERK or other MAP kinases (Figure 10.10). Other studies have linked GPCR/ β -arrestin interactions to effects on the ubiquitination/proteasome pathway. Thus, the diversity of signaling initiated by a GPCR can potentially be very great and can operate over a wide time course. Rapid signaling events can influence the activity of ion channels, electrical excitability and synaptic communication, whereas longer term effects can influence processes such as neuronal gene transcription possibly leading to changes in neuronal structure or phenotype.

A further recent insight into the mechanism of action of GPCRs is that they often act as dimers or other higher order arrays (Milligan, 2004). Homo and heterodimerization of GPCRs has now been frequently reported. These receptor dimers may have properties, including agonist selectivity and signaling, that are unique and that differ from those of receptor monomers. Thus, the overall impact of signaling by GPCRs may be very diverse.

10.5. Synaptic Plasticity

The strength of synaptic communication is not constant. Moment to moment changes in the strength of synaptic transmission underlie the ongoing requirements of neuronal communication and are probably the basis of long lasting phenomena such as learning and memory. We now understand that there are numerous forms of this synaptic “plasticity”. Some forms of plasticity last for brief periods of time whereas others last for many hours or days-perhaps encompassing the lifetime of the organism. In each case changes in the amount of transmitter released, postsynaptic sensitivity to the transmitter or combinations of these processes are involved in

producing these effects. In order to give a general idea as to what these important and widespread neuronal signaling processes involve, we shall discuss two different examples of synaptic plasticity.

10.5.1. Long-Term Potentiation (LTP)

Long-term potentiation and its flip side, long-term depression (LTD), are probably the most intensively studied of all forms of synaptic plasticity (Collingridge et al., 2004 and Figure 10.11). LTP was first observed *in vivo* using rabbits by Bliss and Lomo who demonstrated that a brief high frequency stimulation of the perforant path input to the dentate gyrus of the hippocampus from the entorhinal cortex produced a long lasting (many hours) potentiation of the extracellularly recorded field potential. This phenomenon, or something akin to it, has now been shown to exist at other hippocampal synapses and at many other synapses throughout the brain. Subsequent investigations both *in vivo* and using hippocampal slice preparations revealed LTP to have some interesting properties. For example, if a neuron receives both a weak and a strong input, in which the weak input is not sufficient to produce potentiation, the weak input can be potentiated if it is paired in time with a tetanic

stimulation of the strong input. This property of “associativity” was seen to be a neurophysiological correlate of the proposal made by Canadian psychologist Donald Hebb that coincident activity between two synaptically coupled neurons would cause increases in the synaptic strength between them—a postulate that was made to explain how long-term phenomena such as memory could be represented synaptically. From the point of view of the present discussion the mechanism underlying LTP at many excitatory synapses has been shown to depend on the biophysical properties of NMDA receptors as discussed above. Indeed, the induction of LTP at numerous synapses has been shown to depend both on NMDA receptor activation and the associated influx of Ca^{2+} into the postsynaptic neuron. It will be recalled that the function of NMDA receptors is critically dependent on block by physiological concentrations of Mg^{2+} . Accordingly, when synaptic activity is low and the cell maintains a relatively high resting potential NMDA receptors are blocked. At low rates of presynaptic stimulation the synaptic release of glutamate will result in activation of postsynaptic AMPA receptors. Although AMPA receptor activation will result in some postsynaptic depolarization, this will not be sufficient to relieve the Mg^{2+} block of postsynaptic NMDA receptors, and so no NMDA receptor associated

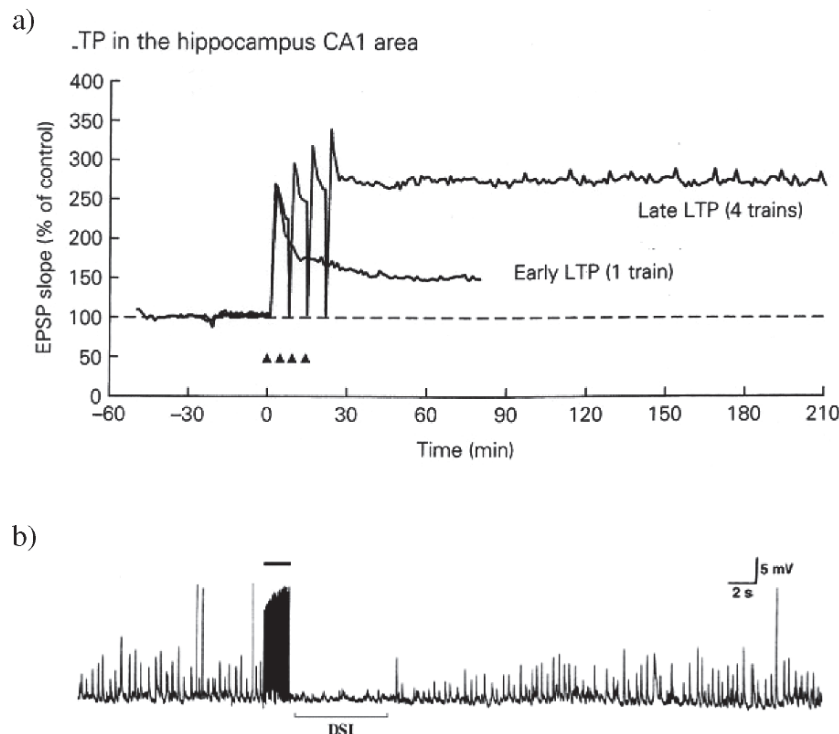

FIGURE 10.11. Examples of receptor mediated synaptic plasticity. (a) Long-term potentiation. (LTP). Synaptic transmission at hippocampal synapses (in this example the CA3/CA1 synapse) is potentiated following application of a tetanus (period of rapid stimulation) to the pre-synaptic nerve. This phenomenon is dependent on the activation of synaptic AMPA and NMDA receptors (see main text). (b) Depolarization suppression of inhibition (DSI). Diagram shows how endocannabinoids produce DSI in the hippocampus. Synaptic potentials recorded as hippocampal neurons are depressed following a tetanus.

current will result. Now consider the situation when a tetanus is applied to the presynaptic nerve resulting in increased glutamate release. The degree of postsynaptic depolarization produced by AMPA receptor stimulation may now be sufficient to relieve the block of NMDA receptors by Mg^{2+} . Once Mg^{2+} leaves the receptor and the receptor is unblocked, its activation by glutamate will not only result in the influx of Na^+ but also that of Ca^{2+} . Subsequent studies have shown that it is this influx of Ca^{2+} that acts as a second messenger stimulating the changes responsible for maintained increases in synaptic function, primarily the insertion of new AMPA receptor subunits into the postsynaptic cell membrane and hence an increase in the strength of glutamate mediated signaling. There are numerous variations on this basic model including observations that, depending on the precise pattern of pairing of synaptic inputs, resulting synaptic transmission may be decreased rather than increased, a phenomenon known as Long-Term Depression (LTD). Thus, synaptic strength at central glutamate synapses can be tuned up or down depending on the overall requirements of the synapse in question, a process dependent on glutamate receptor mediated signaling.

10.5.2. Depolarization-Induced Suppression of Inhibition (DSI)

It has been shown that when the pyramidal neurons of the CA1 field of the hippocampus are depolarized, the inhibitory GABA mediated input to these cells is transiently suppressed (Figure 10.11). This phenomenon is known as “depolarization induced suppression of inhibition” (DSI, Diana and Marty, 2004). As with LTP/LTD described above, phenomena of this type occur widely throughout the nervous system. The mechanism of this effect and its dependence on receptor signaling is interesting. It has been shown that DSI is dependent on the influx of Ca^{2+} into the postsynaptic cell (e.g. the pyramidal neuron in this example). However, this results in a reduction of GABA release presynaptically. This means the signal that is responsible for this effect must be transmitted backwards across the synapse. It will be recognized that this is something that applies to endocannabinoid signaling in the brain. Indeed, it has been shown that DSI can be inhibited by blockers of CB1 cannabinoid receptors (Piomelli, 2003). Thus, the mechanism involved appears to be as follows. Influx of Ca^{2+} into the postsynaptic cell as a result of postsynaptic depolarization, activates endocannabinoid synthesis. The endocannabinoid molecules then leave the cell and diffuse back across the synapse where they bind to CB1 receptors situated on presynaptic terminals. Activation of presynaptic CB1 receptors produces activation of heterotrimeric G-proteins. Binding of the G-protein $\beta\gamma$ subunits to voltage dependent Ca^{2+} channels in the nerve terminal, inhibits these channels. Thus, less Ca^{2+} enters the terminal in response to an action potential and less transmitter is released. The metabolism of the endocannabinoid results in the transient nature of the phenomenon.

Summary

Neurons communicate with each other, as well as with glial cells, through the propagation of action potentials and the release of chemical neurotransmitters across synapses. In this chapter we discuss the molecular processes that are responsible for the electrical excitability of neurons that allows the generation of action potentials as well as the electrical properties of glial cells. The nature of the resting membrane potential in cells and the structure and function of voltage dependent Na, K and Ca channels are discussed. Many different types of substances can act as neurotransmitters. The first neurotransmitter to be discovered was acetylcholine, but now many other substances including biogenic amines and peptides are also known to be neurotransmitters. Conventional neurotransmitters carry information across synapses in an anterograde manner, although some recently defined neurotransmitters such as the endocannabinoids carry information in a retrograde fashion. Neurotransmitters act on different types of receptors. The main classes of receptors are ligand gated ion channels, such as the nicotinic acetylcholine receptor and G-protein coupled receptors, which include the majority of receptors for biogenic amines. Activation of ligand gated ion channels results in a rapid change in the membrane potential, whereas activation of a G-protein coupled receptor can result in numerous changes in ion gradients and second messenger systems. Neurotransmission is not a unvarying process and the strength of synaptic communication can vary on a moment to moment basis – a process known as synaptic plasticity. Different types of synaptic plasticity exist and may involve the participation of receptors for glutamate or for endocannabinoids for example.

Review Questions/Problems

1. **The undershoot of an action potential occurs from**
 - a. Prolonged opening of voltage-activated Na^+ channels
 - b. Opening of voltage-activated K^+ channels
 - c. Inactivation of Na^+ channels
 - d. All of the above
2. **The resting membrane potential is largely influenced by**
 - a. K^+ channels
 - b. Na^+ channels
 - c. none of the above
 - d. all of the above
3. **What is a “selectivity filter” of an ion channel? Do all channels contain a selectivity filter?**

4. **How many pore-forming K⁺ channel subunits assemble to form a functional channel?**
 - a. One
 - b. Two
 - c. Four
 - d. None of the above
5. **Voltage-gated Ca²⁺ channels mediate**
 - a. Fusion of neurotransmitter-filled vesicles in the pre-synaptic terminals
 - b. Repolarization of the action potential
 - c. Generation of the resting membrane potential
 - d. All of the above
6. **Name four properties that you would expect a chemical substance to possess if it functions as a neurotransmitter at a synapse you are investigating.**
7. **What is an “endocannabinoid”? What evidence exists that these substances act as neurotransmitters?**
8. **How many protein subunits does a nicotinic acetylcholine receptor possess?**
 - a. More than one
 - b. Lots
 - c. Five
 - d. Not sure, but definitely around 5 (.....or perhaps 6)
9. **How do ionotropic glutamate receptors regulate the movement of Na and Ca ions into neurons? Why is Ca influx through glutamate receptor channels important?**
10. **What is the basic structure of a G-protein coupled receptor? How does agonist binding to the receptor lead to the activation of heterotrimeric G-proteins?**
11. **Which of the following apply to the arrestin class of proteins?**
 - a. They are scaffold proteins that can bind members of the MAP kinase pathway.

- b. They can sometimes act as receptors for opioid peptides.
- c. They are involved in down regulating the effects of activation of GPCRs
- d. They act as blockers of ionotropic glutamate receptors, or something like that.

Keywords Amacrine cell; Bipolar cell; Cone; Fovea; Horizontal cell; Müller cells; Photoreceptor; Retina; Retinal ganglion cell; Rod

11.1. Introduction

The retina, like other parts of the CNS, derives embryologically from the neural tube. Retinal neurons and glia therefore have many properties in common with other CNS tissue, but they also exhibit specialized response properties and proteins that have evolved to serve the retina's function in transducing light energy into nerve signals and analyzing the visual image. For example, to encode small changes in light intensity, many retinal neurons respond to light with graded changes in membrane potential and do not exhibit sodium-dependent action potentials. In addition to possessing the specialized proteins needed for phototransduction (e.g., rhodopsin and transducin), the retina contains a number of proteins specialized for the transmission and processing of visual information such as the metabotropic glutamate receptor, mGluR6, in ON type bipolar cells; the GABA_c receptor (Lukasiewicz et al., 2004); and the alpha 1F calcium channel subtype in rod photoreceptors. This chapter summarizes some of the special features of retina that help it to transduce and process light.

11.2. Anatomy

The retina is a thin sheet of neural tissue (150–400 µm thick) at the back of the eye upon which the visual image is focused by the cornea and lens (Figure 11.1A). Behind the neurosensory retina is a layer of pigmented epithelial cells known as the retinal pigment epithelium (RPE, Figure 11.1) and beyond the RPE is a dense bed of capillaries within the choroid. Surrounding the choroid is the sclera, made up of densely woven collagen fibers that help to encase and protect the globe.

The retina has a highly organized laminar structure that is similar in all vertebrate species (Figure 11.1B; Dowling, 1987; Rodieck, 1998). It is oriented so that photoreceptors lie at the back, adjacent to the RPE. Thus, to reach the

photoreceptors light must pass through overlying layers of the retina. The photoreceptor (PR) layer consists of the outer and inner segments of rod and cone photoreceptors. Separating the inner segments and photoreceptor cell bodies is the outer limiting membrane (OLM) formed from apical processes of glial Müller cells. The outer nuclear layer (ONL) contains the cell bodies of photoreceptors, which make synaptic contact with horizontal and bipolar cells in the outer plexiform layer (OPL). The inner nuclear layer (INL) contains cell bodies of horizontal, bipolar, and amacrine cells. Synaptic contacts among bipolar, amacrine and retinal ganglion cells are made in the inner plexiform layer (IPL). Anterior to the IPL, closer to the front surface of the retina, is the ganglion cell layer (GCL), which contains cell bodies of retinal ganglion cells. Axons from retinal ganglion cells create a nerve fiber layer (NFL) at the inner surface of the retina. The axons join together as they exit the eye to form the optic nerve, which projects to higher visual centers. The absence of retina and photoreceptors at the optic nerve head creates a small blind spot (Figure 11.1A). The vitreal surface of the retina is bounded by an inner limiting membrane (ILM) formed by Müller cell endfeet.

The retina contains ~60 types of retinal neurons grouped into five major classes: photoreceptors (3–4 types), horizontal cells (2 types), bipolar cells (10–12 types), amacrine cells (~30 types), and ganglion cells (10–15 types) (Masland, 2001; Wässle, 2004). Photoreceptors release L-glutamate to stimulate bipolar cells, which in turn release L-glutamate onto ganglion cells forming a throughput pathway for the transmission of light signals through the retina (Figure 11.2). Horizontal and amacrine cells are predominantly inhibitory interneurons with processes extending laterally in the outer and inner plexiform layers, respectively. As light signals are transmitted from photoreceptors to bipolar cells to ganglion cells, they are modified by inhibitory synaptic feedback from horizontal cells onto photoreceptors and bipolar cells in the outer retina and from amacrine cells onto bipolar and ganglion cells in the inner retina. Photoreceptors and second order retinal neurons (bipolar and horizontal cells) respond to light with graded changes in their membrane potential (Dowling, 1987; but see Kawai et al., 2001). Action potentials are typically observed only in third order neurons of the retina (amacrine and ganglion cells). The use of graded responses by cells early in the visual

FIGURE 11.1. (A) Schematic diagram of a primate eye. (B) Cross section of primate retina showing the different layers.

FIGURE 11.2. The five major retinal cell types (photoreceptors, bipolar cells, horizontal cells, amacrine cells, and ganglion cells) and their synaptic connections.

pathway is likely related to the ability of graded responses to transmit more information than a spike code (Laughlin, 2001). By contrast, the use of action potentials by ganglion cells is necessary to propagate information over the greater distances needed to reach higher visual centers.

11.3. Cell Types

11.3.1. Rod and Cone Photoreceptor Cells

11.3.1.1. Outer Segments and Phototransduction

There are two major types of photoreceptors cells: rods and cones (Ebrey and Koutalos, 2001). The structure and phototransduction proteins of rods are specialized to allow them to respond to dim lights. Cones are less sensitive to light, but provide high acuity and color vision. Rods and cones are named for their rod- and cone-shaped outer segments, respectively. The outer segments of both cell types contain the proteins necessary for phototransduction, packaged into disc-shaped organelles. Cone discs are formed by invaginations of the outer segment plasma membrane whereas rod discs are completely sequestered within the outer segment.

The principal job of photoreceptors is to transduce light into an electrical signal. Phototransduction involves a cascade of enzymes in the outer segment (Arshavsky et al., 2002) (Figure 11.3). It is initiated by absorption of a photon by rhodopsin (or cone-specific opsins). Rhodopsin is a G-protein coupled receptor with homology to other G-protein coupled receptors (GPCRs) (e.g., beta-adrenergic, muscarinic, etc.). However, unlike GPCRs that are activated by the binding of a neurotransmitter ligand, the activating ligand of opsin is a light-sensitive chromophore molecule, vitamin A aldehyde (or retinal), bound within a pocket of the opsin protein. Absorption of a photon by this chromophore initiates a conformational transition of 11-*cis*-retinal, which is bent around the 11-*cis* carbon position, into all-*trans* retinal, which has a straight chain configuration (Figure 11.3). The conformational change in retinal produces conformational changes in the seven *trans*-membrane domains of rhodopsin, causing it to assume an active configuration known as metarhodopsin. The activated GPCR, metarhodopsin, stimulates exchange of GTP for GDP on the associated G-protein, transducin (G_t). Activated alpha subunit of transducin (α_t) stimulates the activity of a cGMP-specific phosphodiesterase, which hydrolyzes cGMP. The plasma membrane of outer segments contains nonselective cation channels permeable to Na^+ , K^+ , and Ca^{2+} that are opened

FIGURE 11.3. The enzymatic cascade responsible for phototransduction.

by the binding of cGMP to their intracellular face. Light-induced reduction in cytoplasmic [cGMP] causes some cGMP-gated cation (CNG) channels to close. When open in darkness, Na^+ and Ca^{2+} influx through CNG channels causes photoreceptors to depolarize. Conversely, light-induced closure of these channels causes photoreceptors to hyperpolarize. Because brighter lights cause a larger number of CNG channels to close, the amplitude of membrane hyperpolarization is graded with intensity.

The enzymatic transduction cascade initiated by photon absorption is terminated by two mechanisms: (1) Light-activated meta-rhodopsin is inactivated in a process that begins with its phosphorylation by rhodopsin kinase. Following phosphorylation of rhodopsin at three sites by rhodopsin kinase, the protein arrestin binds to rhodopsin and arrests further activity. (The actions of rhodopsin kinase are analogous to the regulation of beta-adrenergic receptors by beta-adrenergic receptor kinase.) (2) Light activated transducin is shut down by its intrinsic GTPase activity, which converts GTP into GDP and thereby deactivates the G-protein. The intrinsic GTPase activity of transducin is accelerated by binding of an accessory protein, RGS/G β 5, to the transducin alpha subunit.

Tremendous amplification of the light signal by phototransduction in rods allows them to detect absorption of a single photon (Field et al., 2005). To accomplish this feat, each activated metarhodopsin molecule catalyzes hundred to thousands of transducin molecules and although each transducin activates only a single PDE molecule, every PDE molecule hydrolyzes thousands of cGMP molecules. The net result is that activation of a single rhodopsin molecule by a single photon of light causes the degradation of 10^5 – 10^6 cGMP molecules causing many cGMP-gated cation channels to close and producing a small but detectable change in membrane potential.

Mutations in phototransduction proteins are a major cause of retinitis pigmentosa and other photoreceptor degenerations

(Kennan et al., 2005). Mutations in rhodopsin, phosphodiesterase and cGMP-gated cation channels can all produce retinitis pigmentosa. Mutations in rod-specific transducin produce night blindness whereas mutations in cone-specific transducin produce achromatopsia (rod monochromacy). Similarly, by preventing cones from responding to light, mutations in cone-specific cGMP-gated cation channels also lead to achromatopsia. For an updated list of genes involved in retinal diseases, consult the “Retinal Information Network” (<http://www.sph.uth.tmc.edu/Retnet/>).

11.3.1.2. Light Adaptation

Photoreceptors can respond to only a limited range of intensities before their responses saturate. To maintain responsiveness over the large range of intensities encountered in the world, the phototransduction apparatus adapts its sensitivity to increased light levels to maintain a constant relative response to increments in illumination ($\Delta I/I = \text{constant response}$) (Burkhardt, 2001; Fain et al., 2001). This process of light adaptation is largely due to calcium-sensitive adjustments of the phototransduction enzyme cascade. As mentioned above, cGMP-gated cation channels are permeable to Ca^{2+} allowing Ca^{2+} to enter the outer segments when these channels are open in darkness. This steady Ca^{2+} influx is countered by the extrusion of Ca^{2+} from outer segment by $\text{Na}^+/\text{Ca}^{2+}$ exchangers. The closing of cGMP-gated channels in response to light diminishes the influx of Ca^{2+} but its efflux via the $\text{Na}^+/\text{Ca}^{2+}$ exchanger continues. The concentration of Ca^{2+} in the outer segment therefore diminishes in light. This decrease in $[\text{Ca}^{2+}]_i$ has two main effects on phototransduction: (1) Decreased $[\text{Ca}^{2+}]_i$ enhances the activity of guanylyl cyclase stimulating the production of cGMP. The resulting increase in cGMP opens cGMP-gated channels leading to

depolarization of the photoreceptor membrane potential. (2) Decreased $[Ca^{2+}]$ increases the affinity of cGMP for cGMP-gated cation channels to further promote their opening. The membrane depolarization that results from reopening of cGMP-gated cation channels restores the operating range of the photoreceptor cell, allowing it to hyperpolarize in response to another flash of light.

While calcium-dependent adaptation is sufficient to maintain the sensitivity of cones over a large range of intensities, at extremely high intensities there is also a contribution from photochemical adaptation in which a significant fraction of unbleached chromophore (11-*cis*-retinal) is bleached to all-*trans*-retinal (Burkhardt, 1994). At most light levels, there is a sufficient reservoir of 11-*cis*-retinal in the outer segments so that the bleaching of chromophore molecules does not appreciably limit the sensitivity of the opsin molecule, as long as levels of 11-*cis*-retinal are soon restored. (As presented later, restoration of chromophore levels after bleaching requires participation of the RPE.) However, at extremely high light levels, the rate and amount of bleaching is sufficient to limit the availability of chromophore and thereby limit the sensitivity of opsin to light.

The combined effects of calcium-dependent and photochemical adaptation allow cones to maintain constant incremental sensitivity to light over 10^7 -fold changes in intensity (Burkhardt, 1994). Rods, sensitive to dimmer lights, maintain relatively constant sensitivity over a thousand-fold change in intensity. Rod and cone systems together therefore allow the visual system to perform the impressive feat of maintaining relatively constant incremental sensitivity to light over a ten billion-fold range of intensities. For comparison, pupillary constriction or dilation contributes a 16-fold change in sensitivity, although it has the advantage of being relatively rapid, occurring within a couple hundred milliseconds compared to minutes for full light adaptation.

11.3.1.3. Photoreceptor Inner Segment, Soma, and Synaptic Terminal

The inner segment of photoreceptors is packed with mitochondria that fuel its tremendous metabolic demands. Sodium ions continuously entering the outer segments through cGMP-gated cation channels in darkness are extruded by Na/K-ATPases in the inner segments. The continuous consumption of ATP by these pumps makes photoreceptor cells among the most metabolically active in the body.

Below the inner segment is the soma and nucleus, which connects at its base to the axon and synaptic terminal. Photoreceptors release glutamate at ribbon synapses (Heidelberger et al., 2005). Synaptic ribbons are specialized for sustained release of neurotransmitter and are also found in the terminals of retinal bipolar cells, as well as vestibular and cochlear hair cells. Synaptic ribbons receive their name because of their planar structure in photoreceptor terminals, although bipolar and hair cell ribbons are more spherical in shape.

The ribbon is composed mainly of the structural protein, Ribeye, but also includes a kinesin motor protein, KIF3A, and Rab3-interacting protein, RIM. Ribbons are attached to the synaptic active zone by bassoon, and its structural relative, piccolo. Although the ribbon appears to anchor a readily releasable pool of vesicles, molecular motors do not appear to be involved in vesicle movements near the active zone. RIM protein mutations have been implicated in an autosomal dominant rod-cone dystrophy (Johnson et al., 2003).

Glutamate release from synaptic terminals of photoreceptor and bipolar cells is regulated by calcium influx through L-type calcium channels (Heidelberger et al., 2005). The use of L-type channels at ribbon synapses contrasts with the reliance on N, P, and Q type channels for neurotransmission at conventional synapses of spiking neurons. A retina-specific L-type channel, $\alpha 1F$ (CaV1.4), is localized to rod terminals. Mutations in this channel produce a congenital stationary night blindness (Bech-Hansen et al., 1998).

11.3.1.4. The Fovea

In humans, the center of the visual image is focused on the fovea in the macula lutea, the region of highest acuity in the retina (Kolb et al., 2005). Although primates are the only mammals with a fovea, many birds and lizards also possess a fovea. Unlike more peripheral retina where light must pass through overlying retinal layers to reach the photoreceptors, overlying neurons are displaced at the fovea to diminish light scattering. At the center of the resulting foveal pit, the only structures between the outer segments and vitreal surface are cone axons. Cone axons contain xanthophyll pigments that give the macula lutea its characteristic yellow color. The fovea contains only cones and, at its very center, is even free of blue-sensitive cones. Visual acuity, the ability to resolve fine spatial details, is limited by the spacing between cones in the fovea and the density of cones parallels visual acuity in the retina. Acuity can be as high as 20/10 at the foveal center, but falls off rapidly toward the retinal periphery. Although we are not typically conscious of these movements, the eye is constantly in motion, making small microsaccades to allow the high acuity fovea to scan various points and thus construct a high-resolution image at higher visual centers. Loss of the macular region (e.g., in macular degeneration) thus leads not only to a loss of central vision but also to a general loss of high acuity vision.

11.3.1.5. Cones and Cone Opsins

The retinas of Old World primates have three cone subtypes with different spectral sensitivities: short-wavelength (S or blue-sensitive) cones, middle-wavelength (M or green-sensitive) cones, and long-wavelength (L or red-sensitive) cones. Trichromacy evolved in Old World primates 40 million years ago with duplication of a single M/L ancestral pigment gene followed by divergence into separate M and L pigments. Differences in spectral sensitivity among different cone types arise from the presence of different cone

opsins. Cone opsins are 40% homologous to rhodopsin, S cone opsins are 40% homologous with M and L cone opsins, but M and L cone opsins are 97% homologous with one another. The differences in spectral absorbance among different opsins result from differences in a small number of amino acid residues that alter the position of hydroxyl groups close to 11-*cis*-retinal. The 30 nm difference in spectral absorbance between primate M and L cones is determined primarily by three amino acids: alanine vs. serine at position 180 (~4 nm), phenylalanine vs. tyrosine at position 277 (~10 nm) and alanine vs. threonine at position 285 (~16 nm) (Deeb, 2005).

Different photopigments are encoded by genes located on different chromosomes (Deeb, 2005). The gene for rhodopsin is found on chromosome 3, the S cone pigment gene on chromosome 7, and M and L cone pigment genes on the X chromosome. M and L cone pigments are found in a tandem array on the X chromosome. Recombination between these genes on adjacent X chromosomes is the most frequent cause of color vision anomalies. For this reason, most color vision defects involve red-green color vision and are X-linked recessive. Males with anomalous M or L cone pigments are most common (anomalous trichromats), with a frequency of ~6% among European males, while 2% are entirely lacking in one pigment or the other (dichromats).

11.3.2. Horizontal Cells

Horizontal cells are laterally arborizing interneurons in the outer retina that receive excitatory synaptic inputs from photoreceptors and make inhibitory synapses onto cones and bipolar cells. The neurotransmitter released from horizontal cells is predominantly GABA. A light-evoked reduction of glutamate release from photoreceptors causes horizontal cells to hyperpolarize by reducing the activation of AMPA-type glutamate receptors. With the exception of certain fish retina, there appear to be no NMDA receptors in horizontal cells of adult retina (Thoreson and Witkovsky, 1999). Rats and mice have only one type of horizontal cell, but most other mammals have two types (Masland, 2001). Because both types hyperpolarize to light of all visible wavelengths, they are sometimes referred to as luminosity-type horizontal cells. Many nonmammalian vertebrates have additional chromaticity or color-opponent horizontal cell types that depolarize to certain wavelengths and hyperpolarize to other wavelengths.

Horizontal cells in most vertebrates have large receptive fields due to extensive gap junction coupling among cells. Large receptive fields allow horizontal cells to measure illumination from a wide area. Inhibitory feedback from horizontal cells to cones and bipolar cells subtracts the mean luminance level measured over a wide area from signals transmitted to the inner retina about local luminance changes (Kamermans and Spekrijse, 1999). As discussed later, this negative feedback contributes to formation of the center-surround arrangement of visual receptive fields, important for the detection of edges.

11.3.3. Bipolar Cells

Bipolar cells transmit signals from photoreceptors to ganglion cells. They receive glutamatergic input from photoreceptors, inhibitory influences from horizontal cell contacts at their dendrites in the outer retina, and additional inhibitory inputs from amacrine cell contacts at their terminals in the inner retina. Bipolar cells release L-glutamate at ribbon synapses that contact amacrine and ganglion cells in the inner plexiform layer. There are 9–11 types of cone bipolar cell and a single type of rod bipolar cell in mammalian retina (Masland, 2001; Wässle, 2004). The different cone bipolar cells can be grouped into two major physiological subtypes: cone ON bipolar cells that depolarize to light and cone OFF bipolar cells that hyperpolarize to light. All rod bipolar cells in the mammalian retina are of the ON, depolarizing type. In lower vertebrates, many ON and OFF bipolar cells receive mixed rod and cone inputs.

ON and OFF responses of bipolar cells result from the presence of different glutamate receptors in the two cell types. OFF bipolar cells possess KA and AMPA-type ionotropic glutamate receptors, but not NMDA receptors (Thoreson and Witkovsky, 1999). Thus, like horizontal cells, the synapse from cones to OFF bipolar cells is sign-conserving, that is, light-evoked hyperpolarization of the cone reduces the depolarizing influence of AMPA/KA receptors thereby causing the OFF bipolar cell to hyperpolarize.

ON bipolar cells do not possess ionotropic glutamate receptors but are instead activated by a metabotropic glutamate receptor, mGluR6 (Slaughter and Awatramani, 2002). mGluR6 is a G-protein coupled receptor that acts via the G-protein, G_o , to close nonselective cation channels. Thus, light-evoked cessation of glutamate release from photoreceptors causes these cation channels in ON bipolar cells to open and thereby depolarizes the cell. By contrast with OFF bipolar and horizontal cells, the synapse from photoreceptors to ON bipolar cells is therefore sign-inverting.

ON and OFF bipolar cells excite ON- and OFF-type ganglion and amacrine cells, respectively. ON and OFF pathways remain segregated into the lateral geniculate nucleus (LGN) of the thalamus suggesting this segregation has functional significance. Saturating mGluR6 with the selective agonist, L-2-amino-4-phosphonobutyric acid (L-AP4), produces an acute deficit in the perception of positive contrast (i.e., bright spots on a dark background) (Schiller et al., 1986). It has therefore been suggested that ON bipolar cells preferentially encode information about positive contrast and OFF bipolar cells preferentially encode information about negative contrast. However, ON and OFF bipolar cells can respond equally well to positive and negative contrast steps (Burkhardt, 2001). Furthermore, although mutations in mGlu6 leading to a loss of rod ON bipolar cell function produce night blindness, mGlu6 mutations in ON bipolar cell function do not produce obvious deficits in contrast perception at higher light levels (Dryja et al., 2005). Thus, the role played in contrast perception by the segregation of different ON and OFF pathways remains unclear.

11.3.4. Amacrine Cells

Amacrine cells are laterally interconnecting interneurons and most contain the inhibitory neurotransmitters GABA, glycine or both. Amacrine cells are excited by glutamate released from bipolar cells. This glutamate acts principally on KA and AMPA receptors although many amacrine cells also possess NMDA receptors (Thoreson and Witkovsky, 1999). By anatomical and neurochemical criteria, amacrine cells can be classified into 29 different types (Masland, 2001; Wässle, 2004). With the exception of glutamate, almost every type of neurotransmitter is present in at least one type of amacrine cell. Physiological responses of amacrine cells include transient and sustained depolarizations at light onset (ON cells), light offset (OFF cells), or both (ON/OFF cells). By contrast with the graded light responses of bipolar, horizontal, and photoreceptor cells, many amacrine cells exhibit sodium-dependent action potentials making their responses much more transient.

Many amacrine cells have relatively dedicated functions. Some examples include:

1. Large, radially symmetric starburst amacrine cells help create directional selectivity in directionally selective ganglion cells (Taylor and Vaney, 2003).
2. Dopaminergic amacrine cells with widespread dendritic arborizations increase release of dopamine in response to increases in global illumination. Dopamine diffuses throughout the retina to influence cells as far away as the RPE. The increased release of dopamine by light modifies cell function to optimize retinal responses in daylight (Witkovsky, 2004).
3. All amacrine cells transfer rod signals from rod bipolar cells to ganglion cells (Bloomfield and Dacheux, 2001).

11.3.5. Ganglion Cells

Retinal ganglion cells are the output cells of the retina. Their axons course along the vitreal surface of the retina and bundle together to exit the eye as the optic nerve. Ganglion cells are excited by glutamate released from bipolar cells acting on both NMDA and non-NMDA (KA- and AMPA-type) glutamate receptors (Thoreson and Witkovsky, 1999).

There are 10–15 types of ganglion cells in mammalian retina (Masland, 2001; Wässle, 2004). The two most common types in primate retina are M (magnocellular) cells and P (parvocellular) cells. The various types of ganglion cells remain generally segregated in their projections to the LGN: M ganglion cells project to M cell layers of the LGN, P cells to the P cell layers, and bistratified cells project predominantly to the koniocellular (interlaminar) regions. Primate M and P cells are analogous to Y and X cell types in cat retina.

M cells have large cell bodies and large dendritic arborizations resulting in large receptive fields (Rodieck, 1998). M cells are classified anatomically as parasol ganglion cells. The large receptive fields of M cells limit their contribution to fine

feature analysis. Instead, their output is primarily related to motion and other changes in illumination.

In contrast to M cells, P cells have small cell bodies with small dendritic arborizations resulting in small receptive fields. P cells are also wavelength-selective. P cell output thus contributes to fine feature analysis and color vision. P cells are classified anatomically as midget ganglion cells.

S cones do not provide direct inputs into M and P-type ganglion cells, which receive inputs only from M and L cones. S cones instead provide inputs into two different types of ganglion cells: blue OFF cells and small bistratified blue ON cells.

Recent studies have revealed a population of ganglion cells that are intrinsically light sensitive, that is, they do not require photoreceptor inputs in order to respond to light (Fu et al., 2005). The intrinsic light-sensitivity of these cells is conferred by the presence of the photopigment, melanopsin. Intrinsic light responses of these cells are slow and exhibit minimal adaptation. Although the mechanism of phototransduction employed by melanopsin remains under investigation, early results indicates that it may involve transient receptor potential (TRP) channels similar to those used for invertebrate phototransduction. Thus, intrinsically photosensitive ganglion cells may utilize a more primitive phototransduction mechanism than photoreceptor cells. Melanopsin-containing ganglion cells are very large but few in numbers. They project to the suprachiasmatic nucleus where their tonic responses to light provide important signals for setting circadian rhythms.

11.4. Circuitry

In addition to transducing the incoming light, the retina plays a number of important roles in the initial process of analyzing visual information. In the following section, we consider the retinal circuitry employed for analysis of edges, color, directional selectivity, and scotopic vision.

11.4.1. Edge Detection and Center-Surround Receptive Fields

The detection of contrast edges is enhanced by the center-surround arrangement of receptive fields in cones, bipolar cells, and ganglion cells (Kuffler 1953; Baylor et al 1971). How does this center-surround organization improve edge detection? Consider an ON type ganglion cell (Figure 11.4) in which the circular center of the receptive field is excited by light. Its center-surround arrangement is imparted by the presence of an annular inhibitory region flanking this central excitatory region. A small spot of light illuminating only the excitatory center strongly excites this cell but an annulus of light falling only on the inhibitory surround strongly inhibits it. Full field illumination, which stimulates both the excitatory center and the inhibitory surround, thus produces smaller

FIGURE 11.4. Center-surround arrangement of receptive fields in the retina enhances responses to small spots, edges, and bars of light. (A) Cross section of the center/surround receptive field of an ON center cell. Light falling on the center of the receptive field excites the cell whereas light falling in the periphery produces inhibition. (B) Overhead view of the center/surround arrangement of a receptive field of an ON center ganglion cell illustrating differences in the trains of action potentials evoked by a small spot or full field illumination.

changes in ganglion cell output. A bar or edge of light illuminating the entire excitatory center along with small portions of the inhibitory surround evokes a stronger response than full field illumination, but not as strong as a spot of light illuminating just the excitatory center. The net result of this center-surround receptive field arrangement is that cells respond more strongly to spots, bars and edges than to full field illumination. These same kinds of considerations can be extended to OFF type cells that are excited by light decrements in the center and inhibited by light decrements in the surround. Another way to think about center-surround inhibition is that inhibitory feedback from the broad receptive fields of horizontal and amacrine cells subtracts the mean luminance level from signals transmitted to ganglion cells about local luminance changes. In machine vision, the mathematical equivalent of the center-surround receptive field is implemented to spatially differentiate the image and thus enhance the detection of edges. This is useful in robotics and as a component of artificial visual stimulating systems for visually deprived humans.

11.4.2. Color

The retina initiates the process of analyzing color in the world. The presence of three spectrally distinct types of cones in the primate retina (L, M, and S) provides the physiological basis for trichromatic vision (R, G, and B). The responses of an individual cone do not vary with wavelength, but only with the number of photons absorbed. Thus, one can obtain an identical response from a green-sensitive cone with either green or red light as long as one adjusts the intensities of the two lights to provide equivalent photon capture by the green-sensitive cone. For this reason, color discrimination requires comparisons between inputs from different classes of cones. Synaptic comparisons between dif-

ferent types of cones produce responses that are color opponent, that is, cells that respond to one wavelength by depolarizing but to another wavelength by hyperpolarizing. In nonmammalian vertebrates, color opponency is evident in horizontal and bipolar cells (Twig et al., 2003). In mammalian retinas, color opponency is first detected in ganglion cells (Dacey and Packer, 2003).

There are red/green and blue/yellow opponent cell types in the retina. These two classes of opponent neurons contribute to the perception of color opponent after-images (e.g., the illusory appearance of red produced after gazing steadily at a field of green). In primate retina, the red/green hue axis of color vision utilizes separate retinal circuits and ganglion cell types from the blue/yellow axis. Red/green opponency in primate P-type ganglion cells arises from the selective segregation to center and surround of M and L cone inputs via distinct bipolar cells (Dacey and Packer, 2003). Via specialized S cone bipolar cells, S cones provide the input for responses to blue light in the receptive field center of blue ON bistratified and blue OFF-type ganglion cells. Responses to yellow light in the receptive field surround are generated from a sum of L and M cone signals.

11.4.3. Directional Selectivity

Some magnocellular ganglion cells are excited by stimuli moving along one axis of the receptive field (e.g., upward) but show little response to stimuli moving in the opposite direction (e.g., downward). Surprisingly, directionally selective ganglion cells with directional asymmetries in their receptive field receive their main synaptic inputs from symmetrically radiating starburst amacrine cells (Taylor and Vaney, 2003). Starburst amacrine cells provide both excitatory (cholinergic) and inhibitory (GABAergic) inputs into ganglion cells. The

directional selectivity in postsynaptic ganglion cells results from the fact that cholinergic excitation from starburst amacrine cells occurs earlier than GABAergic inhibition when visual stimuli move in the preferred direction, but GABAergic inhibition precedes excitation when stimuli move in the opposite, nonpreferred direction. Thus, GABAergic inhibition more strongly dampens the response of the ganglion cell to stimuli moved in the nonpreferred direction compared to the preferred direction. The mechanisms responsible for this asymmetric synaptic output of acetylcholine and GABA from starburst amacrine cells remain under investigation.

11.4.4. Rod Pathways

Scotopic or low-light vision is mediated by rod photoreceptors. The mammalian retina has a duplex organization in which rods communicate with ganglion cells using a largely separate circuit from cones. The primary rod circuit begins with rods communicating with ON-type rod bipolar cells that, unlike cone bipolar cells, do not contact ganglion cells directly but instead contact AII amacrine cells. AII amacrine cells form gap junctions with cone ON bipolar cell terminals and inhibitory, sign-inverting glycinergic synapses with cone OFF bipolar cells. Output from AII amacrine cells, therefore, feeds rod signals into cone bipolar cells driving both ON and OFF center ganglion cells. AII amacrine cells provide the primary pathway for rod signals at very low light levels, but at higher light levels there is also a contribution from direct rod inputs into OFF bipolar cells and the transmission of rod signals through gap junctions into neighboring cones (Bloomfield and Dacheux, 2001).

There is tremendous synaptic convergence in the rod pathway with as many as 75,000 rods converging onto a single ganglion cell. By contrast, cones show much less convergence, with a 1:1 connection of cones to midget bipolar cells to midget ganglion cells in the foveal center. This difference accounts for the high visual acuity mediated by cone circuits. On the other hand, the large convergence of signals in the rod pathway facilitates the perception of very dim flashes of light. The ability of individual rods to respond to a single photon of light combined with convergence allows us to perceive the absorption of as few as a dozen photons within 100 ms (Field et al., 2005).

11.5. Glia

The predominant retinal glial cell is the Müller cell. Müller cells are radial glia that span the retina from the OLM to ILM and ensheath virtually every cell in the retina. They play a number of important roles in maintaining homeostasis (Newman and Reichenbach, 1996). For example, Müller cells are a primary storage depot for glycogen in the retina that can provide metabolites (e.g., lactic acid) to neurons during times of metabolic stress. Müller cells also help to remove and redistribute metabolic waste products. They exhibit high levels of glutathione that can help protect the retina from oxidative stress. Müller cells also possess Na/HCO₃ cotransport

mechanisms and carbonic anhydrase to stabilize pH levels in the retina.

Another important role of Müller cells is the spatial redistribution of K⁺ from regions of high concentration to regions of low concentration in order to maintain a stable extracellular K⁺ concentration of about 3 mM (Kofuji and Newman, 2004). When neuronal depolarization causes K⁺ levels to increase in the IPL and OPL, excess K⁺ ions enter Müller cell processes. K⁺ influx in the plexiform layers is accompanied by a simultaneous efflux through K⁺ channels clustered at the vitreal surface and along blood vessels. Conversely, a reduction in K⁺ accompanying neuronal hyperpolarization is accompanied by an efflux of K⁺ out of Müller cells into the plexiform layers. The current flowing through radially oriented Müller cells as a result of this spatial buffering of K⁺ produces measurable *trans*-retinal potentials, such as slow PIII of the electroretinogram. It was once believed that Müller cell K⁺ currents were the predominant mechanism responsible for the ERG b-wave, but more recent studies suggest that the b-wave primarily reflects ON bipolar cell responses.

Müller cells are major sites for the uptake and removal of neurotransmitters, most notably glutamate and GABA. Glutamate transport into neurons is smaller and slower than transport into Müller cells and thus uptake into Müller cells is the principal mechanism responsible for the initial removal of extracellular glutamate following synaptic activation (Pow, 2001). In addition to neurotransmitter transporters, Müller cells possess neurotransmitter receptors and can release neuroactive substances (e.g., ATP) (Newman, 2004). Thus, activity of retinal neurons can influence Müller cells and Müller cell activity can in turn influence adjacent neurons.

The retina also contains three other types of glia: astrocytes, oligodendrocytes and microglia. Retinal astrocytes are located primarily in the NFL and oligodendrocytes form the myelin sheath of axons in the optic nerve. Hematopoetically derived microglia are small stellate cells that, when quiescent, associate with inner retinal blood vessels.

Infection or damage to the retina stimulates Müller cell gliosis (Garcia and Vecino, 2003) and migration of microglia to the injured area to assist in phagocytosing debris from dying cells. Microglia and Müller cells both release cytokines in response to injury but the release of proinflammatory cytokines can sometimes exacerbate cell damage during retinal disease. Cytokines released by Müller cells include vascular endothelial growth factor and transforming growth factor beta, which promote neovascularization, as well as basic fibroblastic growth factor. At least in some species, Müller cells respond to injury and cytokines by dedifferentiating into progenitor cells that can give rise to neurons (Fischer and Reh, 2003).

11.6. Retinal Pigment Epithelial Cells

The RPE is a monocellular epithelium of hexagonal cells whose name reflects the facts that it contains melanin pigment granules and forms the outermost layer of the retina. The apical processes of RPE cells ensheath the outer segments of rods and

cones and each RPE cell contacts 20–30 rods (Marmor and Wolfensberger, 1998; Strauss, 2005). Melanin granules are concentrated in the apical processes and cytoplasm of RPE cells but are nearly absent from basal cytoplasm. By absorbing stray photons of light that have passed through photoreceptor outer segments, melanin granules improve the optical isolation of individual photoreceptors.

Neighboring RPE cells are connected by tight junctions that help to create the blood/retinal barrier separating the neurosensory retina from fenestrated capillaries in the choroid. The basement membrane of RPE, together with the adjacent basement membrane of the choroid, forms a structure known as Bruch's membrane. RPE cells possess a number of organic and ion transporters to help move polar molecules across the blood retinal barrier. These include transporters for amino acids, folate, ascorbic acid, myo-inositol, organic anions, glucose and lactate.

Photoreceptors continually synthesize new phototransduction proteins for incorporation into newly formed outer segment discs. As new discs are formed at the base of the outer segment, older discs are phagocytosed by RPE cells at the tip of the outer segment. Each outer segment disc is formed and shed in ~2 weeks. The phagocytosis of discs occurs in circadian bursts (rods at the end of night, cones at the end of day).

The bleached, all-*trans* form of the chromophore retinal cannot be converted back into photosensitive 11-*cis*-retinal within photoreceptor cells but requires participation of the RPE (Lamb and Pugh, 2004). After the conversion of 11-*cis*-retinal to all-*trans*-retinal by light, all-*trans*-retinal is rapidly converted to all-*trans*-retinol (all-*trans*-vitamin A) in the photoreceptor outer segment. All-*trans*-retinol is then transported out of the photoreceptor cell, through the interstitial space separating the photoreceptor outer segments and RPE, and into the RPE via a process involving interstitial retinoid binding proteins (IRBP). Upon entering the RPE, retinol is bound to cellular retinol binding protein. All-*trans*-retinol is converted to 11-*cis*-retinol by retinol isomerase (RPE65) and 11-*cis*-retinol is converted back to 11-*cis*-retinal (11-*cis*-vitamin A aldehyde) by 11-*cis*-retinol dehydrogenase. 11-*cis*-retinal is transferred to cellular retinal binding protein (CRalBP) for transport to the RPE cell surface. Finally, regenerated 11-*cis*-retinal is transported back to photoreceptors via IRBP. By depriving photoreceptors of chromophore, mutations of proteins in the visual cycle (e.g., retinol isomerase [RPE65], 11-*cis*-retinol dehydrogenase, CRalBP, and IRBP) can lead to photoreceptor degeneration.

The interstitial space between RPE and photoreceptors contains a sticky interphotoreceptor matrix consisting of glycoproteins, proteoglycans, and hyaluronic acid that helps the retina adhere to the back of the eye. Retinal adhesion is also promoted by extrusion of water from the RPE to choroid. Basolateral Cl channels and apical Na/K/2Cl transporters are particularly important for water transport out of the RPE. Because photoreceptors are not physically bound to the RPE, the retina can detach from the RPE with a strong blow to the eye, fluid build-up behind the retina (rhegmatogenous

detachment), or traction from overlying cells in proliferative vitreoretinopathy. Detachment of photoreceptor cells from the adjacent RPE prevents recycling of the photopigment which blocks phototransduction by depriving opsin of sufficient chromophore. Unless repaired, retinal detachment therefore results in blindness.

One by-product of photoisomerization in photoreceptor outer segments is A2E (*N*-retinylidene-*N*-retinylethanolamine). A2E is ingested by RPE cells when they phagocytose outer segments. However, A2E cannot be enzymatically degraded by RPE cells and thus accumulates in these cells, where it becomes a major component of lipofuscin granules (Sparrow and Boulton, 2005). Stargardt's macular degeneration involves a defect in the ABCR transporter that increases accumulation of A2E suggesting it may play a role in macular degeneration. The damage to the RPE associated with A2E accumulation may result from stimulation of apoptosis in A2E-laden RPE cells produced by exposure to blue light.

A major risk factor for age-related macular degeneration (ARMD) is the presence of drusen deposits (Zarbin, 2004). White drusen spots visible with an ophthalmoscope are formed by deposits between the RPE and Bruch's membrane. Drusen formation involves inflammatory reactions and RPE cells overlying drusen often show signs of impending cell death. Studies on genetic factors contributing to ARMD have singled out mutations in complement factor H as a major risk factor (Edwards et al., 2005; Haines et al., 2005; Klein et al., 2005). This has led to the suggestion that mutations in complement factor H promote an over-active inflammatory response that contributes to drusen formation leading to RPE cell damage and ARMD.

11.7. Blood Supply

Blood is supplied to the retina by the central retinal artery and choroidal blood vessels (Oyster, 1999). The central retinal artery arises from the ophthalmic artery, which in turn branches off the internal carotid artery. Upon entering the retina, the central retinal artery branches into deep capillary beds in the INL and superficial capillary beds in the GCL. Endothelial cells of retinal capillaries are joined by tight junctions, contributing to the blood/retinal barrier. There is little or no autonomic regulation of the retinal circulation; blood flow through these capillaries is instead primarily controlled by autoregulation (Wangsa-Wirawan and Linsenmeier, 2003). Retinal capillaries drain into the central retinal vein.

Choroidal vessels derive from posterior and short posterior ciliary arteries that, like the central retinal artery, branch off from the ophthalmic artery. The choroidal circulation forms a dense bed of fenestrated capillaries, known as the choriocapillaris, adjacent to the basolateral surface of the RPE. The flow rate through the choriocapillaris is among the highest in the body and the arterio-venous drop in PO₂ is minimal. This high flow rate supplies the energetically demanding photoreceptors with large amounts of oxygen and maintains the retina

at a constant temperature despite changing levels of radiant energy focused onto the back of the eye. Oxygen for the photoreceptors comes primarily from the choroid. The high level of oxygen consumption by photoreceptor cells in darkness produces a PO_2 of zero at the level of the inner segments in mammalian retina (Linsenmeier, 1986). Under these conditions, there is no oxygen available for the remainder of the retina from the choroid. Other retinal neurons instead receive their oxygen from the retinal circulation. (By contrast with mammals, many cold-blood vertebrates lack retinal capillaries and rely on the choroid to supply the entire retina with oxygen and other nutrition.) While capable of autoregulation (Kiel and Shepherd, 1992), blood flow in the choroicapillaris is also regulated by autonomic inputs. Choroidal capillaries drain into four vortex veins, one from each quadrant of the eye.

Summary

The retina is an outpost of the CNS with neuronal structures and proteins specialized for the transduction of light signals into a neural code that the brain can interpret. Mutations of proteins involved in phototransduction or synaptic transmission through the retina produce visual deficits ranging from subtle color vision defects to complete blindness. Although normally isolated from blood-mediated immune responses by the blood-retinal barrier, inflammatory responses, including gliosis and those mediated by the complement system, are important contributors to retinal degeneration, particularly ARMD. Studying immune responses in the retina and their pharmacological manipulation therefore presents a promising avenue for the treatment and prevention of retinal degeneration.

Review Questions/Problems

1. Briefly summarize the major steps in phototransduction in rods.
2. What are the calcium-dependent steps in light adaptation?
3. What are the major physiological features of the two most common types of retinal ganglion cells in the primate retina?
4. In mammalian retina, which capillary beds supply oxygen to the photoreceptors and which to the remaining parts of the retina?
5. For an ON-type ganglion cell, describe how the center-surround organization of visual receptive fields improves edge detection.
6. Describe the mechanisms responsible for directional selectivity in retinal ganglion cells.
7. Describe the rod pathway used in scotopic vision.
8. Describe the key enzymatic steps in the visual cycle converting bleached all-*trans*-retinal back into light-sensitive 11-*cis*-retinal.
9. Describe the spatial redistribution of K^+ by Müller cells.
10. Summarize the enzymatic mechanisms by which phototransduction is terminated after photostimulation.
11. Which of the following is the predominant glial cell type in the retina?
 - a. Astrocyte
 - b. Müller cell
 - c. Microglia
 - d. Schwann cell
 - e. RPE cell
12. In which layer of the retina do bipolar cell terminals contact ganglion cell dendrites?
 - a. Outer nuclear layer
 - b. Outer plexiform layer
 - c. Inner nuclear layer
 - d. Inner plexiform layer
 - e. Ganglion cell layer
13. Which of the following statements is true about the fovea?
 - a. The fovea contains both rods and cones
 - b. The fovea is the region of the retina where ganglion cell axons exit the eye.
 - c. The fovea is the region of the retina responsible for the highest acuity vision in humans and primates.
 - d. The location of the fovea on the retina is not a fixed anatomical feature but varies with focus.
 - e. At the center of the fovea, light must first pass through ganglion, amacrine, horizontal and bipolar cells before reaching photoreceptor outer segments.
14. Upon which chromosome are genes for M cone pigments located?
 - a. X chromosome
 - b. Y chromosome
 - c. Chromosome 3
 - d. Chromosome 7
 - e. Chromosome 10
15. Which of the following statements is true about ON and OFF type retinal bipolar cells?
 - a. ON bipolar cells possess KA/AMPA receptors and OFF bipolar cells possess NMDA receptors.
 - b. ON bipolar cells possess NMDA receptors and OFF bipolar cells possess mGluR6.
 - c. ON bipolar cells possess mGluR6 and OFF bipolar cells possess NMDA receptors.

- d. ON bipolar cells possess mGluR6 and OFF bipolar cells possess KA/AMPA receptors.
- e. ON bipolar cells possess KA/AMPA receptors and OFF bipolar cells possess mGluR6.

16. Which of the following is NOT considered to be a major role of Müller cells?

- a. Spatial redistribution of potassium
- b. Neurotransmitter uptake and removal
- c. Homeostatic maintenance of retinal pH levels
- d. Glycogen storage
- e. Promoting retinal adhesion to the back of the eye

17. Which of the following is NOT considered to be a major role of RPE cells?

- a. Phagocytosis of injured cells
- b. Formation of blood-retinal barrier
- c. Absorption of stray light
- d. Photopigment recycling
- e. Phagocytosis of outer segment discs

18. Which of the following proteins is a major constituent of synaptic ribbons?

- a. Retinol dehydrogenase
- b. Melanin
- c. Ribeye
- d. RGS/Gβ5
- e. Bestrophin

19. Which of the following is the main reason that retinal detachment leads to blindness?

- a. The retina dies from oxygen deprivation after separating the retina from the choroidal blood supply.
- b. Separation of the RPE and photoreceptor outer segments prevents visual pigment recycling.
- c. Retinal detachment shears off photoreceptor outer segments because they are covalently bound to the RPE.
- d. Photoreceptors die because of the inability of the RPE to phagocytose photoreceptor outer segments.
- e. Retinal detachment moves the retina out of the optical plane of focus.

20. What is the light-sensitive molecule found in intrinsically photosensitive retinal ganglion cells of mammalian retina?

- a. Melanopsin
- b. Transducin
- c. Rhodopsin

Keywords Antibodies; B cells; Effector memory T cells; Follicular dendritic cells (FDCs); Immune privileged; Regulatory T cells; Stat4; Stat6; T-Bet

12.1. Introduction

The immune system maintains the integrity of the human body by recognition and elimination of new antigens coming from outside and inside generated modified substances. The control of immune reactions to infections, tumors and degeneration in the brain is different than in other tissues. The differences in immune control in the brain became clear with the development of transplantology. In 1873 Dutch ophthalmologist van Dooremaal observed prolonged mouse skin graft survival in the dog eye, and later in 1948 Sir Peter Medawar, while trying to explain success of corneal homograft transplantation, performed classic transplantation of skin to the brain and anterior chamber of the eye of non-immunized or immunized rabbits (previously transplanted with the same donor's skin sample to the chest). He highlighted two mechanisms involved in the immunologic control in brain: existing systemic immunity to donor's skin and the status of vasculature. Tissue grafted in the brain or eye survived longer than in any other place in the body without sensitized lymphocyte infiltration via new vessels of the graft. A few more places in the human body obtained definition of "privileged" sites (testis and a placenta) based upon immune tolerance to the graft. Only direct transplantation/injection allows backward introduction of "unknown" antigens. This process in brain parenchyma (not meninges and choroids plexes) is also different than in non-privileged sites due to the absence of endogenous professional antigen-presenting cells capable to trigger immune responses (Hart and Fabre, 1981), and because of the specific properties of non-professional antigen-presenting microglial cells in parenchyma (Matyszak and Perry, 1996; Matyszak, 1998). However, *in situ* inflammation induced by pathogens or abnormal proteins

with complementary peripheral adaptive immune responses will induce brain damage and appearance of tertiary lymphoid structures (Aloisi and Pujol-Borrell, 2006). The role of professional antigen-presenting cells, microglial cells and regulatory T cells in these events will be reviewed in other chapters (4, 9, 18–24, 37, 42, 46).

As of today, the control of immune reactions in the brain attributed mostly to the specific cell membrane-bound molecules, soluble factors and brain-associated immune deviation (BRAID) reviewed by (Niederkorn, 2006).

In this chapter we will review the development and function of lymphocytes, which include T cells (thymus derived), B cells (associated with antibody production) and natural killer (NK) cells (effectors of innate immunity).

The specialized functions of lymphocyte subsets are reflected in the differing patterns of molecules and genes they express. These molecules often underlie the unique function of the subsets they mark. For instance, CD3 defines T cells because it is an essential component of the TCR complex; CD4 is associated with MHC class II recognition, mostly in "helper" (Th) responses, whereas CD8 is associated with MHC class I recognition and cytotoxic responses, and B cells are defined by their immune globulin (Ig) expression or production. Immunological research during much of the 1980–1990 era was directed at identifying and characterizing leukocyte markers, first through mAb production, and then through gene sequencing. This led to the discovery of most of the CD molecules that are used today to mark leukocyte subsets and define subset function (<http://www.pathologyoutlines.com/cd100300.html>).

The final stage of lymphocyte differentiation is antigen-specific memory cells. Only these cells are capable of surveillance in the brain. The mechanisms of surveillance of perivascular and parenchymal sites are reviewed in the following articles (Ransohoff et al., 2003; Engelhardt and Ransohoff, 2005).

It is important to discuss lymphopoiesis and lymphocyte function before discussing lymphocyte-CNS interactions during diseases of the nervous system in this textbook.

12.2. Overview of Embryonic Lymphopoiesis

Today, the common concept of lymphoid tissue ontogeny results from the understanding that circulating stem/progenitor cell populations migrate from the yolk sac into the aorta-gonad mesonephros (AGM), then into organ anlagen, to initiate hematopoiesis in fetal liver and bone marrow, bursa of Fabricius, spleen and T cells lymphopoiesis in the thymus. The generation of lymphocytes from adult hematopoietic stem cells (HSCs) is different from embryonic development and will be discussed separately. Our knowledge about ontogeny of the immune system developed mainly from studies on mice, where the performing of *in vivo* experiments to test precursors activities of certain cell populations was possible. By contrast, most information about human lymphopoiesis came from *in vitro* studies. The principles outlined in mouse models seem to be generally consistent with some underlining mechanisms of human lymphoid system development, but the cell surface phenotypes of human transitional cell populations are often different from those in the mouse.

12.2.1. T Cells

The thymus is a primary lymphoid organ involved in the development of T cells. T cells are primary effectors of adaptive immune responses. The human thymus develops from the endoderm at approximately embryonic day 35. The thymic epithelium and surrounding mesenchyme derived from the cephalic region of the neural crest play an important role in T cell development. The epithelium undergoes morphological changes, beginning to express high levels of major histocompatibility class (MHC) II complex and of epidermal growth factor-like transmembrane protein Delta 1. This protein interacts with the Notch receptors from the family of epidermal growth factor-like transmembrane proteins that control different aspects of tissue development and homeostasis, and plays a critical role in T cell development.

At the embryonic stage, lymphomyeloid commitment precedes thymic development in CD45⁺CD117⁺CD34⁺ hematopoietic clusters of AGM region. In addition, multi-lineage progenitors restricted to T, NK and macrophage lineage (pTM) or just T lineage (pT), or B and B plus macrophage (pBM) were identified in the AGM region. At the time of entry into the thymic epithelium, immigrant cells express CD45⁺, CD117⁺, CD44⁺, CD34⁺, and α 4 integrin, but are negative for CD62L, CD25, and Thy-1.2 in mice. An important cytokine that regulates survival of human lymphoid progenitors is interleukin (IL)-7 (see Chapter 15). Before exposure to epithelial inductive influence by thymic epithelial stromal cells (TEC), lymphomyeloid progenitors express the alpha chain of the IL-7 receptor). Upon differentiation into functionally mature lymphocytes (CD4 and CD8), IL-7R α appears to be downregulated and cells lose thymic homing capacity. The transmembrane receptor Notch is essential during early

T lineage development. In the absence of Notch1-mediated signals, T cell development is arrested at an early stage and B cells accumulate intrathymically.

12.2.2. B Cells

B-lymphocytes are generated during a lifetime by differentiation from hematopoietic stem progenitors. At the mature stage, they possess a system that can sense the presence of microorganisms and contribute to their destruction by secreting immunoglobulins (Igs). The precise site of B cell commitment in ontogenesis is not known. The B cell precursors derive from the intraembryonic para-aortic region. B cell commitment might take place in the omentum and fetal liver. These progenitors express CD117⁺AA4.1⁺CD34⁺CD45⁺CD19⁺Sca-1⁻. Fetal liver has long been considered the initial site of B cell commitment, and from then on B progenitors expand in a synchronous wave-like pattern reaching a peak in the perinatal stage. Even after birth B cells may develop at sites other than the bone marrow. The myeloid suppressing transcription factor Pax-5 plays a critical role in B cell commitment, while the chemokine receptor CXCR4 and its ligand SDF-1 α play a pivotal role of B cell development in the fetal liver (see Chapter 13.)

12.2.3. NK Cells

Natural killer (NK) cells are one component of the innate immune system and have the ability to both lyse target cells and provide an early source of immunoregulatory cytokines. As with B cells, the precise site of NK cell commitment in ontogenesis is not known. The population of fetal liver CD34⁺CD38⁺ cells contains committed NK precursors, which are unable to develop into T cells. The fetal thymus also contains an immature CD34⁺CD5⁺CD56⁻ population with a clonogenic NK cell potential, as well as T/NK precursors with bipotentiality. The general consensus is that the bone marrow is the site for NK development in adults.

12.2.4. Cells Derived from Hematopoietic Precursors and Involved in Immune Responses in the Brain

Brain tissue contains only one type of specialized resident cell of macrophage lineage called microglia. Several waves of population in the brain by cells of macrophage lineage have been proposed: primitive macrophages from yolk sac with high proliferation capacity, myeloid precursors from fetal liver with ability to proliferate, and bone marrow derived non-dividing (or very limited division) precursors in adult. Two types of resident brain macrophages, microglia and perivascular macrophages, exist with non-selective, but differently expressed human markers. Both types are CD45^{lo}CD11c⁺CD11b⁺(Mac-1^{+/+})CD64^{+/}-CD68^{+/}-RCA-1^{+/+}-MHC-classII^{+/+}-Ham56⁺ and function in the immune system as effectors of innate immunity. Microglia and perivascular macrophages are major participants in the establishment of adaptive immune reaction and immune privilege

in situ in the parenchyma and the meninges. The nature of microglia and other brain residents from monocyte lineage will be explored in Chapter 9.

12.3. Postnatal Development of Lymphocytes

12.3.1. Hematopoietic Stem Cells

The generation of lymphocytes from adult HSCs is different from embryonic development. HSCs are defined by their unique capacity to self-renew as well as their ability to differentiate into all blood cell lineages. Therefore, transplanted HSCs are crucial for reconstitution of hematopoiesis in patients following bone marrow (BM) ablation. Although representing approximately only 0.05–0.1% of total BM cells, virtually all HSCs activity has been shown to be contained within the lineage negative or low ($Lin^{-/lo}$) $Sca1^{+}c\text{-Kit}(CD117)^{lo/hi}$ (LSK) $CD34^{-/lo}$ HSC compartment. The LSK HSC pool can be further subdivided for short-term repopulating cells using

additional markers. As HSCs begin to express high levels of CD34, CD27 and another tyrosine kinase type receptor, Flk-2/Flt3, they lose long-term repopulating activity.

To date it is still unclear whether the four lymphoid lineages—T, B, NK, and DCs develop from common lymphoid progenitors (CLPs, Figure 12.1), or whether they are derived from either lymphoid-restricted stem cells or multipotent progenitors. However, at least in the adult murine bone marrow, a population of $Lin\text{-}IL\text{-}7R^{+}Thy\text{-}1^{-}Sca\text{-}1^{lo}CD117^{lo}$ cells has been shown to contain CLPs. This has been determined by their capacity to develop into lymphoid cells while being unable to support myeloid differentiation. It is possible that between common myeloid precursors (CMP) and granulocyte monocyte precursors (GMP), exist a population of progenitors for monocytes and dendritic cells (MDP), that are positive for CX₃CR1 (fractalkine receptor) (Fogg et al., 2006). These novel progenitors give rise to monocytes, to several subsets of macrophages, and to steady-state $CD11c^{+}CD8^{+}$ and $CD11c^{+}CD8^{-}$ dendritic cells *in vivo*. They are devoid of lymphoid, erythroid, and megakaryocytic potential and, also lack granulocyte differentiation potential.

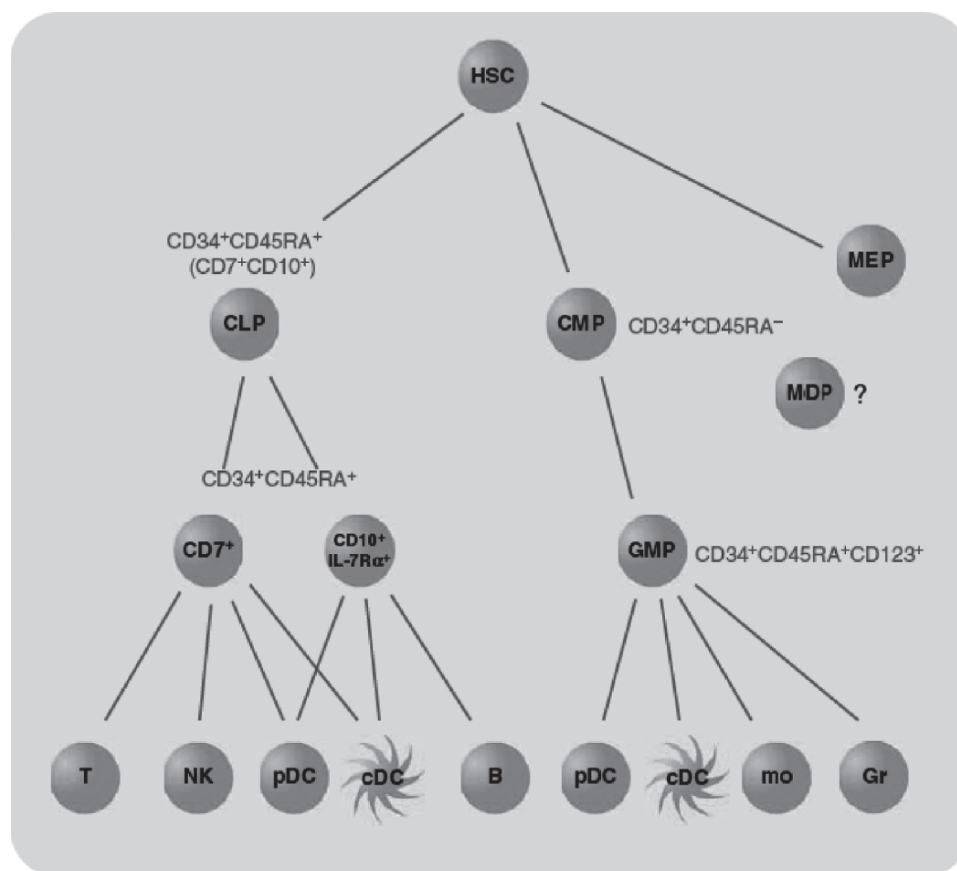

FIGURE 12.1. Model for lymphocytes development. Modified from Blom and Spits (2006).

12.3.2. T Cells Development, TCR, MHC, and CD4-CD8 Commitment

Postnatal lymphomyeloid progenitors are present in bone marrow and circulate in the blood. They do not express IL-7R α . Expression of this receptor reappears on CLP in adult bone marrow before entry into the thymus and final commitment to T cells. The thymus does not provide an environment for self-renewal. Seeding of the thymus with bone marrow progenitors is required to maintain thymopoiesis throughout adult life. CD25⁻ (IL-2 receptor alpha chain) and CD117⁺ expression have been used to characterize progenitor migration from blood into the thymus. Intrathymic development of T cells is based on three major sets of genes: promiscuous tissue-specific antigen (TSA) expression on thymic epithelial cells (TEC), MHC class I and II molecules expression on antigen-presenting cells (APC) such as cortical TEC, medullary TEC, thymic dendritic cells (DCs) and macrophages, and T cell receptor (TCR) molecule expression on mature T cells.

12.3.2.1. The Thymic Epithelial Cells

The nature of TEC precursors and pathways of maturation is still under debate. The most accepted concept today is that TEC come from the self-renewing precursors of endoderm origin, positive for expression of keratin 5 and 8. TEC precursors cells undergo a maturation pathway beginning as cortical TEC (cTEC) without expression of a transcriptional regulator known as an autoimmune regulator (AIRE), advancing to an immature medullary TEC (mTEC) with low levels of AIRE expression, then maturing into mTEC AIRE-positive cells, and finally into Hassall's corpuscles. TEC express tissue-specific antigens representing all parenchymal organs, and including up to 5–10% of all currently known genes, including fetal stage-, tumor- and sex-associated genes. TSA expression increases with TEC maturation. Brain-, intestine- and liver-related TSA have the highest presentation on mTEC. TECs do not form a static scaffold, but similar to stratified epithelia of the skin and gut have a steady state turnover with a half-life of 3–4 weeks. Together with a turnover rate of two weeks for thymic DCs, this makes the APC population in the medulla a highly dynamic compartment (Derbinski and Kyewski, 2005). Those, mTEC and thymic DCs play a central role for the establishment of central tolerance (Kyewski and Klein, 2006).

Interaction with TEC is the major step in T cell education in the thymus and in establishment of self-tolerance. The cross-talk between derived early T lineage progenitors (ETPs) with MHC II-positive cTEC gives rise to CD4⁺CD8⁻ double/dominant negative (DN) thymocytes. DN thymocytes undergo proliferative expansion, lose B- and NK potential and commit to T cell lineage with the onset of TCR β -chain rearrangement. Following T cell lineage commitment, positive selection occurs through the interaction of now CD4⁺CD8⁺ double positive cells with cTEC bearing MHC I and II. Cross-talk between mTEC and DCs expressing TSA leads to deletion (or induction of

anergy) of self-reacting T cells, a process known as negative selection. Negative selection results in the generation of CD4 or CD8 positive T cells. Maturation of ETPs into CD4 or CD8 T cells take place in corticomedullary junction and medulla. Following education and establishment of self tolerance, single positive CD4 or CD8 cells leave the thymus (Bommhardt et al., 2004). However, the ectopic expression of antigens on mTEC is very low and several are not expressed at all. Indeed, it seems unbelievable that a tiny population of mTEC could realistically reproduce the tremendous antigenic diversity created by post-translational modifications, alternative mRNA splicing and differential peptide processing. Moreover, intrathymic gene expression cannot induce tolerance to the broad range of innocent external antigens derived from flora or food. It was proposed that thymus-tropic DCs that patrol the periphery and then return to the blood might constitute a mechanism to prevent misguided T cell responses toward at least some of these unpredictable antigens. Normal blood contains small numbers of circulating differentiated DC, which can capture blood-borne microorganisms. These DCs use a classical multistep adhesion cascade for homing to the thymus through microvessels in the corticomedullary junction (Bonasio et al., 2006). They can induce antigen-specific clonal deletion and participate in maintaining central tolerance to brain-born antigens throughout human life as well as participate in the induction of regulatory T cells for establishment of acquired peripheral tolerance (Goldschneider and Cone, 2003). Intrathymal expression of brain antigens such as putative multiple sclerosis (MS) autoantigens B-crystallin, S100, proteolipid protein (PLP) spliced variant, but not myelin oligodendrocyte glycoprotein (MOG)- α and MOG- β isoforms were found in the medullary compartment in humans (Bruno et al., 2002). During ontogeny, oligodendrocytes first express the fetal form termed golli-MBP, which postnatally is replaced by the adult form, termed classic MBP. The switch from golli-MBP to classic MBP does not occur in mTECs. Instead, golli-MBP remains the predominant transcript throughout adulthood, possibly favoring self-tolerance to epitopes present in this isoform (Kyewski and Klein, 2006). Thus, T cells specific for epitopes encoded only by the full-length form of PLP or classic MBP, respectively, may escape intrathymal selection and contribute to the initiation and maintenance of the early phase of multiple sclerosis (Chapter 18, 21).

12.3.2.2. T Cells Receptor and CD4/CD8 Commitment

Signaling through the T cell receptor controls key events in the life of T cells: their development in the thymus from common lymphoid progenitors, the survival of naive T cells following their exit from the thymus, and the differentiation of these cells into effector populations with discrete functional profiles. Mature T cells express either as $\alpha\beta$ - or $\gamma\delta$ -T-cell receptors that recognize specific antigens. These receptors are generated by a rearrangement of gene segments that result in

the formation of genes encoding the α -, β -, γ -, and δ -chains of the receptors.

The choice of $\gamma\delta$ vs. $\alpha\beta$ chains of TCR expression happens at the stage of pre-TCR by selection of cells with productive TCR β rearrangements irrespective of the V β gene segment used. Rearrangement of TCR generates receptors with different affinity and avidity to an unlimited amount of peptides (derived from self and non-self proteins) in the context of MHC molecules expressed on thymic APC/TEC.

Thymocyte fate and selection are related by the degree of TCR downregulation and internalization after TCR/peptide/MHC engagement. Maximal TCR downregulation is correlated with negative selection (highest avidity, agonists), and suboptimal TCR downregulation is correlated with positive selection (lowest avidity, antagonists). Intermediate stages in development of early thymocytes from triple negative (CD3⁻CD4⁻CD8⁻) into double positive (CD3⁺CD4⁺CD8⁺) are presented in Table 12.1.

Further lineage commitment is directed by cellular interactions with MHC molecules. Cellular interaction with MHC class I antigens generates CD8 cells. Interaction with MHC class II antigens generates CD4 cells (reviewed in Kappes et al., 2005). The Lck protein tyrosine kinase activity upon “strong” TCR signaling favors development of CD4⁺ cells, whereas “weak” TCR signaling and reduction of Lsk activity favors development of CD8⁺ cells. TEC and thymic hematopoietic DCs are able to induce the proliferation and differentiation of CD4⁺CD8⁻CD25⁻T cells into CD4⁺CD25⁺FOXP3⁺ (forkhead box P3) regulatory T cells (Treg). This induction depends on peptide/MHC class II interactions, and the presence of IL-2 (Watanabe et al., 2005).

TABLE 12.1. Markers for intermediate stages in T cell development.

Abbreviation: TSP, thymus seeding progenitors; ETP, early thymic progenitor; ISP, immature single-positive progenitor, icTCR, intracytoplasmic TCR; EDP, early double-positive

These mature, but naive T cells exit peripheral blood and seed lymphoid organs in T-cell specific zones to be acquired by adaptive immune responses for elimination of infected or tumor cells, support for humoral immune responses, formation of immunologic memory, prevention of excessive tissue damage, and facilitation of tissue regeneration (see Chapter 12).

12.3.2.3. NKT-Cell Development

One lineage choice that occurs rather late in T-cell ontogeny is the development of NKT cells. NKT cells express markers of both NK cells and T lymphocytes. These include Ly49 family receptors NK1.1 and TCR in mice. Mature NKT cells are CD44^{hi}CD69⁺, a phenotype consistent with an activated cell. A hallmark of NKT cells is copious IL-4 and IFN- γ secretion promptly upon TCR activation. Because of this property, NKT cells most likely possess regulatory functions. They suppress multiple autoimmune phenomena, and in some cases, inhibit tumor metastases. Unlike conventional $\alpha\beta$ T cells that are selected by classical MHC class I and II, the vast majority of NKT cells are selected by the non-polymorphic class I-like molecule, CD1d.

NKT-cell development is dependent on the protease cathepsin L. As NKT cells react to lipids, cathepsin L may process a lipid carrier protein that is required for loading lipids onto CD1d. A strong candidate for the lipid carrier protein is prosaposin, a precursor that is cleaved into a series of lipid transfer proteins. As the structure of lipids capable of binding CD1d is not as diverse as peptides, it is perhaps not surprising that NKT cells exhibit a limited TCR repertoire. The CD1d-restricted NKT cells also differ from mainstream T cells in co-receptor expression. They are CD4⁺ or double negative, and never CD8⁺.

12.3.2.4. T Cells and Brain

The long living neurons and synapses that provide long-term memory have to be strongly protected from damage by inflammatory/autoreactive CD4⁺ and cytolytic/cytotoxic CD8⁺ T cells. Brain parenchyma does not support migration or survival of naïve T cells (Hickey, 2001). The highly specialized nature of the cerebral vasculature endothelial cell lining with tight junctions provides a diffusion barrier for hydrophilic molecules (see Chapter 38) and forms a physical barrier to lymphocytes. However, lymphocytes capable to enter perivascular spaces, without disruption of this barrier via emperipolesis (Engelhardt, 2006). Moreover, a small amount of memory T cells predominantly consisted of CD4⁺/CDRA⁻/CD27⁺/CD69⁺ activated central memory T cells expressing high levels of CCR7 and L-selectine are present in cerebrospinal fluid of patients with noninflamed CNS (Engelhardt and Ransohoff, 2005). Choroid plexus stroma always contains CD3⁺ T cells (Kivisakk et al., 2003). These cells represent a circulating pool of long living lymphocytes and express other tissue specific homing determinants, such as skin homing molecules cutaneous leukocyte antigen (CLA) and CCR4 chemokine receptor and gut tissue committed determinants integrin $\alpha 4\beta 7$ and CCR9 chemokine receptor (Kivisakk et al., 2006).

For a short period of time, T cells can be found in perivascular spaces and make parenchymal foci as an inflammatory reaction to acute viral or bacterial infection, during autoimmune and degenerative diseases (see Chapters 18–24). However, such physiologic responses in the brain parenchyma are quickly terminated by neuron-produced gangliosides via the downregulation of MHC class I and II co-stimulatory molecular expression on glial cells (Massa, 1993). Several soluble factors can suppress activation and proliferation of T cells in response to local antigens presented by microglia. For example, vasoactive intestinal peptide (VIP), which is a neurotransmitter in the suprachiasmatic nucleus, modulates T cells differentiation, and affects the profile of cytokine secretion by cells of macrophage lineage (Delgado et al., 2002). During inflammation in the brain a wide spectrum of anti-inflammatory and immunosuppressive substances were observed: IL-10, TGF- β , indoleamine dioxygenase, prostaglandins etc. T cells could be eliminated from brain parenchyma by apoptosis mediated by Fas-Fas ligand (CD95/CD95L) interaction. Fas ligand is constitutively expressed throughout the CNS (neurons, astrocytes, oligodendrocytes, microglia, and vascular endothelium), and its expression increases in response to inflammation. Antigen-priming and activation of lymphocytes also stimulates expression of CD95 (the receptor for Fas ligand). Through Fas-Fas-L interaction, endothelial cells as well as astrocytes, prevent access of activated T cells (Choi and Benveniste, 2004).

Lymphocyte behavior in brain tissue depends upon functional status of microglial cells, parenchymal and perivascular macrophages.

Activation of brain microglial cells, DCs and macrophages may also be stopped by factors directly produced by neurons, such as CD200 molecules. This protein from the Ig superfamily plays an important role in the downregulation of myeloid cell function, which expresses a receptor to this ligand. Another soluble factor chemokine, fractalkine, produced by neurons and astrocytes, downregulates inflammatory activity of microglia/macrophages via its receptor CX3CR1 (Cardona et al., 2006; Charo and Ransohoff, 2006).

Persistence of T cells in the brain is a rare event and is associated with chronic pathology forming tertiary lymphoid structure that provides support and activation signals by DCs and macrophages. These structures are present in perivascular spaces, meninges and choroid plexus, and were studied mostly in multiple sclerosis (see Chapter 18).

12.3.3. B Cells

12.3.3.1. Development in Bone Marrow

In adults, B cells are generated from B-lineage committed precursors in the bone marrow (BM). Newly formed B cells express antigen-specific surface antibodies (sIgM⁺ and sIgD⁺). In the BM, B cells are subjected to multiple selective pressures that purge autoreactive B cells and guide differentiation of the remaining cells into functionally distinct peripheral B cell compartments (Table 12.2). Naive B cells then enter the circulation and migrate to the spleen and lymph nodes.

The generation of B-lymphocytes from HSCs is controlled by two cytokine receptors (Flk2/Flt3 and IL-7R) and six transcription factors (PU.1, Ikaros, E2A, Bcl11a, EBF, and Pax-5). Ikaros and PU.1 act in parallel pathways to control the development of lymphoid progenitors, in part, by regulating the expression of essential signaling receptors Flt3, CD117, and IL-7R α . Generation of the earliest B cell progenitors depends on transcriptional factors E2A and EBF that coordinately activate the B cell gene expression program and immunoglobulin heavy-chain gene rearrangements at the onset of B-lymphopoiesis. Pax5 restricts developmental options of lymphoid progenitors to the B cell lineage by repressing transcription of lineage-inappropriate genes and by simultaneously activating expression of B-lymphoid signaling molecules. Two other transcriptional factors LEF1 and Sox4 contribute to the survival and proliferation of pro-B cells in response to extracellular signals. Finally, IRF4 and IRF8 together control the termination of pre-B cell receptor signaling, and thus, promote differentiation to small pre-B cells undergoing light-chain gene rearrangements (Singh et al., 2005). Productive variable-region and joining-region rearrangements (V_LJ_L rearrangements) of the immunoglobulin light chain are completed in pre-B cells. Expression of the B-cell receptor (BCR) drives pre-B cells to the immature B-cell stage. Newly formed B cells are exported to peripheral lymphoid tissues as functionally immature or transitional intermediates cells.

12.3.3.2. Distribution of B Cells and Function

Selection of newly formed B cells to transitional, follicular and marginal-zone (MZ) B cells depends on integrated signals from several classes of surface receptors such as, the BCR and co-signals, the tumor-necrosis factor receptor (TNFR) family, and the G-protein-coupled receptors (GPCRs).

Follicular and MZ long-lived compartments participate differentially in B-cell effector functions such as the germinal-

centre (GC) reaction, long-term memory, antigen presentation, and antibody and plasma-cell (PC) generation. Different strengths of BCR signaling are required for the development of the three mature B-cell subsets: peritoneal B cells require the strongest BCR signal, follicular B cells require an intermediate BCR signal, and marginal-zone B cells require a weaker BCR signal.

During B lymphocyte development, antibodies are assembled by random gene segment re-assortment to produce a vast number of specificities. A potential disadvantage of this process is that some of the antibodies produced are self-reactive, and in humans, the majority (55–75%) of all antibodies expressed by early immature B cells display self-reactivity, including polyreactive and anti-nuclear specificities. Most auto-antibodies are removed from the population at discrete checkpoints during B cell development. Inefficient checkpoint regulation would lead to substantial increases in circulating auto-antibodies. So, an important role of the BCR at the immature B-cell stage is to induce efficient elimination of these potentially harmful cells. This can be achieved in three ways: immature B cells are eliminated through negative selection (BCR-induced cell death), immature B cells are inactivated (anergy), or immature B cells revise the specificity of their BCRs (receptor editing).

12.3.3.3. Brain and B Cells

In contrast to T cells, in different immunopathologies, the brain provides a fostering environment to B cells. Primary central nervous system (CNS) lymphomas are usually of B cell origin. The cerebrospinal fluid (CSF) of patients with chronic infections and autoimmune diseases of the CNS typically contains remarkably stable oligoclonal Ig bands. In the CNS of multiple sclerosis patients, clonally expanded B cells and plasma cells persist. Ectopic B cell follicles develop in the meninges of patients with secondary progressive MS, and B cell differentiation may be recapitulated in the CNS of MS patients (Krumbholz et al., 2006) (see Chapters 18–24).

12.3.4. Adult NK Cells

Human NK cells comprise ~15% of all lymphocytes and are defined phenotypically by their expression of CD56 and lack of CD3 expression. Two distinct populations of human NK cells can be identified based upon their cell-surface density of CD56. The majority (~90%) of human NK cells have low-density expression of CD56 (CD56^{dim}) and express high levels of Fcγ receptor III (FcγRIII, CD16), whereas ~10% of NK cells are CD56^{bright}CD16^{dim} or CD56^{bright}CD16⁻ (Table 12.3).

Over the past decade a number of phenotypic and functional properties of human NK cells have been characterized. There is now good evidence to suggest that distinct immunoregulatory roles can be assigned to the CD56^{bright} and CD56^{dim} NK-cell subsets. Peripheral NK cells express, in addition to CD16 and CD56, CD161 (NKR-P1A). Low-affinity FcγRIII on the surface of NK cells binds to Ab-coated (opsonized)

TABLE 12.3. Markers for NK cell development.

targets and signals through associated subunits containing an immunoreceptor tyrosine-based activation motif (ITAM) and directs antibody-dependent cellular cytotoxicity (ADCC).

Of significance, the CD56^{bright} NK-cell subset expresses the high-affinity IL-2R constitutively and can produce interferon gamma (IFN-γ) in response to picomolar concentrations of IL-2. Since IL-2 is produced only by T cells and not NK cells, the expression of high-affinity IL-2Rαβγ on CD56^{bright} NK cells is necessary to promote cytokine cross-talk between NK cells and T cells in secondary lymphoid organs. NK cells constitutively express several receptors for monocyte-derived cytokines (monokines), including IL-1, IL-10, IL-12, IL-15, and IL-18, and most likely receive some of their earliest activation signals from monocytes during the innate immune response.

12.4. Organization of the Secondary Lymphoid Tissues

12.4.1. Embryonic Development of Lymphoid Tissues

Development of the lymphatic system begins with the invagination of endothelial cells from veins and the formation of lymphoid sacs. At the location of the lymph sacs, connective tissue protrudes into these lymph sacs, forming the very first anlagen of the lymph nodes. At this moment, differentiation of mesenchymal cells into specialized cells, known as lymphoid organizer cells, initiates the formation of lymph nodes.

Platelet-derived growth factor (PDGF), fibroblast growth factor, as well as TGF superfamily of growth factors, all of which are crucial for the differentiation of mesenchymal cells, are likely to be involved in the earliest phases of lymphoid organ formation. However, no molecules have been identified that direct the early specification of mesenchymal cells into specific lymph node organizer cells.

Mesenchymal specification of lymph node organizer cells is expected to be independent from lymphotoxin beta receptor (LT-βR) signaling. Stromal organizer cells mediate attraction and retention of hemopoietic cells (lymphoid tissue inducers, LTi), resulting in accumulation and clustering of cells (Mebius, 2003; Cupedo and Mebius, 2005).

For the generation of LT α i cells from IL-7R-expressing hematopoietic precursors, expression of retinoic-acid-receptor-related orphan receptor- γ (ROR γ) by LT α i cells is mandatory. LT α i cells trigger the LT- β R on stromal cells through expression of LT $\alpha_1\beta_2$. LT $\alpha_1\beta_2$ is induced by ligation of either the TNF-related activation-induced cytokine (TRANCE) that signals through TRANCE receptor (TRANCER) and/or IL-7R. Functional LT α i cells need to express CXCR5 as well as CCR7 to respond to chemokines involved in lymph node formation such as CXCL13, CCL19, and CCL21.

During the generation of functional lymphoid tissue organizers, LT- β R signaling leads to expression of mucosal addressin cell adhesion molecule (MAdCAM-1), intercellular adhesion molecule 1 (ICAM-1), and vascular cell-adhesion molecule 1 (VCAM-1) on endothelial cells, as well as the production of the chemokines CXCL13, CCL19, and CCL21 by stromal cells and HEVs (Carlsen et al., 2005).

A few days before birth, lymphocytes and dendritic cells (DCs) are recruited to the lymph-node and Peyer's-patch anlagen. Because T cells and B cells themselves express LT- $\alpha_1\beta_2$, recruitment of lymphocytes is amplified by a second positive-feedback loop and culminates in the formation of a mature lymph node or Peyer's patch consisting of segregated T-cell zones and B-cell follicles, HEVs and additional specialized mesenchymal cells.

IL-7R signaling has been reported to be essential for the development of Peyer's patches, but this pathway is also involved in the generation of some lymph nodes. In the absence of a functional components of the IL-7R signaling pathway such as IL-2R common γ -chain (γ_c) and Janus kinase 3 (Jak3) or in the absence of IL-7, peripheral lymph nodes do not develop. Although lymphopenia has been suggested as an explanation for the inability to detect lymph nodes in IL-7R-deficient and γ_c -deficient mice, lymph nodes can easily be found in severe combined immunodeficient (SCID), recombination-activating gene (Rag) 1 product and Rag2-deficient mice, which also lack mature lymphocytes.

Inducer, precursor CD45⁺CD4⁺CD3⁻ cells also differentiate into antigen-presenting cells, as well as natural killer cells, but not to B or T cells. Detailed phenotyping of adult LT α i (or accessory) CD45⁺CD4⁺CD3⁻ cells has shown that they are similar to a CD4⁺ cell population.

12.4.2. Lymph Node Architecture

Lymph nodes have two components: the stroma with its fixed cells and the parenchyma with its migrating cell populations. In contrast to non-lymphoid parenchymal organs, the stromal network has an indispensable functional role.

Fibroblastic reticular cells (FRCs) constitute the main stromal population and form its internal three-dimensional network. FRCs express surface molecules and produce "homing" chemokines for T cells, B cells, and DCs. FRCs provide anatomical arrangements that influence the traffic patterns of lymphocytes facilitating lymphocyte "crawling" along pre-

formed "corridors". Moreover, FRCs typically wrap reticular fibers (mainly made up of type III and IV collagen, elastin and laminin) to form a set of interconnected channels called the FRC conduit system.

This system allows for efficient and rapid transfer of soluble molecules, such as antigens, chemokines and immune complexes from the subcapsular sinus to the deeper cortex, the high HEVs, and perhaps the follicular compartment.

Lymph nodes can undergo rapid and profound hypertrophy during an immune response, and FRCs are deeply involved in matrix reorganization and the remodeling of lymph node architecture.

The conduit system and sinuses are lined by sinus endothelial cells (SECs). SECs are flattened cells that do not form a continuous layer, especially in the wall of the medullary sinus, but contain intercellular gaps or pores. Gaps have also been demonstrated in the floor of the subcapsular sinus. FRCs and SECs might be ontogenically related and serve to filtrate lymph fluid collected from all peripheral tissues, including brain interstitial tissue and cerebrospinal fluid.

In the subcapsular sinus, macrophages and DCs sample the lymph and remove microorganisms and debris contained there. FRCs and SECs cells also transport and/or process antigenic material for presentation to B and T cells. However, soluble lymph-borne material can restrict access to the lymphocyte compartment and the cortex.

Migrating naive T and B cells enter lymph node via HEVs, migrate through the net of dendritic cells and exit via single (one) for each nodule efferent lymph vessel back to circulation. Soluble antigen and circulating DCs enter via afferent lymphatic vessels at multiple sites along the capsule. All secondary lymphoid tissues have some structural similarity where the major component is a lymphoid follicle with germinal center, follicular mantle and marginal zone (Figure 12.2).

12.4.3. Antigen-Presenting Cells in Lymph Node

The lymph node harbors a composite population of dendritic cells (DCs)—residents and emigrants—capable of selection, stimulation and elimination of effector lymphocytes. These cells trigger adaptive immunity and/or tolerance. In the human lymph node T-cell compartment, two primary subsets of DCs, compared to six in mice, have been identified: monocytoïd CD11b⁺CD11c⁺ and plasmacytoïd interferon (IFN)- α producing CD123⁺CD11b⁺CD11c⁻. The last subset clusters with T cells around HEVs.

CD11c⁺ DCs are present as stellate cells whose delicate processes or "veils" extend in many directions, these are called interdigitating DCs.

In the B cell compartment, follicular DCs (FDCs) orchestrate B cell function. Whether FDCs originate from hematopoietic progenitors or from stromal elements is still a controversy. New evidence suggests the presence of two types of FDCs within the human germinal centers: the classic FDCs

FIGURE 12.2. Pathways of lymphocytes selection and migration. Modified from Von Andrian and Mackay (2000).

that express CD21 and fibroblast-related markers represent stromal cells and the CD3⁺CD4⁺CD11c⁺ germinal center dendritic cells (GCDC) that represent hematopoietic cells and may be analogous to the antigen-transporting cells described in mice.

Under specific conditions *in vitro*, human monocytes can downregulate expression of the hematopoietic marker CD45 and function as FDCs (Heinemann and Peters, 2005). For example, FDCs are generally considered to be the major source of CXCL13 (also called B cell-attracting chemokine-1) both in normal and aberrant lymphoid tissue. The most CXCL13-expressing cells in rheumatoid arthritis and ulcerative colitis are of monocyte/macrophage lineage. They are located not only in irregular lymphoid aggregates within an FDC network but also within and near smaller collections of B cells in diseased tissue where no FDCs are detected.

The same type of macrophage-derived FDCs could support B cells in multiple sclerosis patients (Krumbholz et al., 2006).

These cells occupy the outer layers of primary and secondary lymph node follicles—the light zone and the follicular mantle. FDCs constitute a three-dimensional sponge-like network formed by interdigitation of adjacent cells. As shown by

ultrastructural studies, these cells present filiform or beaded dendrites with characteristic “ball-of-yarn” convolutions.

FDCs play a pivotal role in promoting B-cell proliferation and differentiation in germinal centers. They are very efficient in trapping and retaining antigen–antibody complexes through CD21–CD35 and FcγRIIB receptors for long periods and presenting them as iccosomes (immune-complex-coated bodies) to memory B cells. More details of lymph node functional organization were described in several reviews (Von Andrian and Mempel, 2003; Crivellato et al., 2004).

Spleen also contains lymph node-like organized structures, however this organ is multifunctional. For detailed information read Cupedo and Mebius’s (2005) review.

12.4.4. Lymph Node as the Home for Primary Adaptive Immune Responses and Peripheral Tolerance

12.4.4.1. Common Rules of Adaptive Immune Responses

The major function of the immune system is the control of our biologic individuality. The strength and quality of immune

responses is based on highly polymorphic MHC molecules and various recombinations of T and B cell receptors.

Cytokine/chemokine milieu induced by external, self and self-modified proteins, loaded into DCs/macrophages and delivered from affected tissues (including the brain) by lymph into regional draining lymph nodes controls the balance between induction of immunity or tolerance. Both the induction of antigen-specific immunity and tolerance rely on the direct interaction of DCs with naive T cells. These interactions occur in the T cell zone of lymph nodes in the vicinity of high endothelial venules (Von Andrian and Mackay, 2000).

12.4.4.2. *CD4⁺ Cell Polarization*

Depending on the co-stimulatory and cytokine signals that are provided by DCs at the time of priming, naive CD4⁺CD25⁻ T cells differentiate into the different types of helper cells (Th1, Th2, and T follicular helper). Activation of naive CD4⁺ T cells through the TCR elicits low but detectable transcription of both genes IL-4 and IFN- γ . Expression of the T-box transcription factor, T-bet, plays a critical role in Th1 development and supports transcriptional competence at the IFN- γ locus and selective responsiveness to IL-12. As stimulation progresses in the presence of signaling through the essential IL-12 receptor (via transcription factor STAT4), primed cells express IL-2 and become Th1 helper cells.

Another transcriptional factor GATA3 is involved in Th2 differentiation and contributes to chromatin remodeling events that favor IL-4 gene stable demethylation and IL-4 production. Signaling through IL-4 receptor, and downstream with STAT6, favors stable production of IL-4 (as well as IL-5, IL-13) and differentiation in Th2 cells (Ansel et al., 2003; Kalies et al., 2006). It is unclear whether Tfh cells differentiate as a separate lineage at the time of T-cell priming or whether they emerge at a later stage from non-polarized, primed T cells or even from polarized Th2 or Th1 (less possible) cells.

12.4.4.3. *CD4⁺ Cells Interaction with B Cells*

A proportion of newly primed T cells with upregulated expression of CXCR5 migrate toward the T-cell-zone-follicle boundary where they might provide cognate help to antigen-specific B cells. In this location they can interact with B cells and also with CD4⁺CD3⁻ accessory cells (LTi cells analogs for development of lymph nodes). The CD4⁺CD3⁻ accessory cells present at the T-cell-zone-follicle boundary and within the follicles provide signals through CD134 (also known as OX40) and CD30 at the surface of follicular T cells to direct localization of these cells, maintenance of germinal-centre reactions and the generation of B-cell and CD4⁺ T-cell memory responses.

These follicular T cells strongly express the CD28-related molecule ICOS (inducible T-cell co-stimulator; also known as CD278) and secrete moderate amounts of IL-10, CD278, and IL-10 act as co-stimulatory factors having crucial functions in T helper cell and B-cell responses. After stimulation follicular

T cells express CD134 and rapidly upregulate CD40 ligand (CD40L; also known as CD154) from pre-formed stores. This is consistent with their capacity to induce germinal-centre B cells to survive, secrete antibody and express activation-induced (cytidine) deaminase (AID). AID is crucial for immunoglobulin class switching and somatic hypermutation. IL-21 co-stimulation potently induces the expression of both B lymphocyte-induced maturation protein-1 (BLIMP-1) and AID, as well as the production of large amounts of IgG from B cells (Ettinger et al., 2005).

Tfh, Th1, and Th2 cells can all participate in antibody responses. Th1 and Th2 cytokines guide class-switch recombination regulating/determining particular immunoglobulin classes and subclasses, thereby skewing antibody responses depending on the nature of the stimulus. For example, IFN- γ promotes switching to IgG2a during antiviral responses while IL-4 promotes the production of IgE during anti-parasite responses. Both Th1 and Th2 cells are crucial helpers in the extrafollicular pathway of B-cell differentiation and are potent inducers of class switching to T-cell-dependent antibody classes and subclasses outside germinal centers.

CD4⁺ Treg cells suppress Th1/Th2 cells function, the expansion of CD8⁺ cells and B-cell production of antibody. These are CD4⁺CD25⁺CD57⁻ T cells that co-express CXCR5 and localize to T cell zone and germinal centers. T cells that express NK1.1 (CD4⁺NKT cells) as well as NK are there.

12.4.4.4. *B Cells Differentiation and Humoral Immune Responses*

The help that T cells provide to B cells allows for the production of high-affinity memory B cells and long-lived plasma cells specific for foreign antigens. T cell independent immune responses usually occur after direct activation of B cells by bacterial capsular polysaccharides and by microorganism-derived Toll-like-receptor (TLR) ligands. TLR-stimulated T cell independent response is a rapid antibody response to the pathogens through the generation of short-lived, low-affinity extrafollicular plasma cells.

The essential structure for T cell-dependent responses is a germinal center. Germinal centers arise in lymphoid tissues following antigenic stimulation and provide a milieu for proliferation of B cells (known as centroblast). Somatic hypermutation in germinal centers results in increased affinity for antigen in a minority of germinal-center B cells. This process can also generate self-reactive B cells.

Centroblasts exit the cell cycle to become centrocytes and bind antigens that are associated with FDCs using newly expressed cell-surface immunoglobulins. After processing, B cells present antigen in MHC II to T helper cells and elicit help. Interaction with T helper cells has several outcomes: (1) survival and selection of high-affinity centrocytes; (2) class-switch recombination of immunoglobulin and differentiation into long-lived plasma cells and memory B cells; (3) perpetuation

of germinal-center reactions by stimulating centrocytes to recycle and become centroblasts. In the absence of antigen-specific T cells, centrocytes are eliminated and germinal centers abort early after induction.

Spontaneous ectopic germinal-center formation has long been recognized to occur in human autoimmune diseases and is a source of somatically mutated high-affinity autoantibodies.

12.4.4.5. *NK Cells in the Lymph Node*

NK cells are present in secondary lymph nodes, in which they exert important immunoregulatory functions. In humans, NK cells make up as much as 5% of all mononuclear cells in peripheral lymph nodes. These NK cells belong to the CD56^{bright} subgroup, and are mainly cytokine producers in the T-cell area, where they can interact with DCs. They provide IFN- γ for Th1 polarization and act as messengers between innate and adaptive immunity. NK cells are also capable of modulating the function of DCs either by inducing their maturation or by killing them.

12.4.4.6. *CD8⁺ T Cells in the Lymph Node*

A small proportion of follicular T cells in human germinal centers are CD8⁺ (less than 5% in tonsils and 10–15% in lymph nodes). Unlike B cells, which require a significant amount CD4⁺ T cell help in order to achieve high specificity, magnitude and stability in antibody production (humoral immune responses), CD8⁺ cell mediated (cytotoxic/cytolytic) cellular immune responses during the first several days after induction are independent from CD4⁺ help. Only memory formation is dependent on CD4⁺ T cell help. Mainly it depends upon CD40 ligation and IL-2 production by CD4⁺ Th1 helper cells and is regulated by co-stimulatory molecules expressed by DCs.

The effector CD8⁺ T cells possess an arsenal of cellular weapons and are exquisitely refined in their ability to recognize target cells displaying small peptides on a protein scaffold of MHC. Upon recognition of a foreign peptide, CD8⁺ T cells can use either cytopathic or non-cytopathic mechanisms to rid a cell of an invading pathogen. These mechanisms include deposition of pore-forming molecules and granzyme release, engagement of the apoptosis-inducing ligands (such as Fas ligand), and the release of cytokines such as IFN- γ and TNF- α . All this machinery is programmed in the lymph node during priming and delivered at the site where CD8⁺ cells perform their function. CTLs will eliminate virally or bacterially infected cells (stromal, macrophages/DCs, or lymphocytes) residing in lymph nodes that would have led to lymphopenia and immune-suppression (HIV/AIDS).

12.4.4.7. *Memory Formation and Vaccines*

Some polarized antigen-specific CD4⁺ T cells (Th1, Th2), antigen-primed CD8⁺ upregulate the expression of receptors for pro-inflammatory chemokines such as CXCR3 (CXCL9, -10, -11, known as α -chemokines IP-10, Mig, I-TAC) and down-

regulate CCR7 (lymphoid tissue homing), in order to exit from lymph nodes for immediate participation in peripheral effector responses (von Adrian and Mackey, 2000). In affected tissues, Th1 cells will produce large amounts of IL-2, IL-12 p40, and IFN γ promoting effector function of CD8⁺ cytotoxic lymphocytes. Th2 cells will produce large amounts of IL-4, IL-5 and IL-13, but not IFN- γ , promoting humoral responses, inflammation and elimination of the pathogen. Most effector cells will die after an antigen is cleared, but a few antigen-experienced memory cells remain for long-term protection. Different subgroups of memory cells stand guard in lymphoid organs and bone marrow in order to patrol peripheral tissues and to be able to mount rapid responses whenever the antigen returns.

The carrier development for T as well B cells is probably programmed during priming, and involves T-T, T-B cell cooperation on the basis of DC co-stimulatory signals. Signaling via CD40, CD27, 4-1BB (CD137), inducible co-stimulatory molecule (ICOS) in the presence of IL-7, IL-15 and IL-21 facilitates the development of memory cells in lymphoid and non-lymphoid tissues. Approximately only 5–10% of effector cells will pass through and generate stem-cell-like capacity for self-renewal, long-term antigen-independent persistence and protective immunity (>20 years). Some of these cells will persist in non-lymphoid tissues after elimination of pathogens (including brain tissue).

Generation of such memory cells is the goal of vaccination against viral and bacterial infections. Today, the best way to achieve this goal is vaccination using attenuated live pathogens.

12.4.4.8. *Tolerance*

Under normal conditions in normal tissue, liters of interstitial fluid containing lipids, proteins, peptides, apoptotic debris (including brain tissue) and most likely immature dendritic cells loaded with such compounds, pass through lymph nodes. Immature DCs continuously sample and present non-pathologically modified autoantigens to T cells. Due to the low expression levels of class I and class II MHC and co-stimulatory B7-family proteins on immature DC, productive immune responses are not possible. Instead, the cognate T cells undergo limited activation/expansion followed by programmed death, or obtain anergic/tolerant status to the self antigen.

Different types of regulatory cells also actively contribute to the programming and maintenance of peripheral tolerance by production of IL-10 and TGF- β family cytokines.

The stimulatory effects of CD28 ligation are counteracted by the co-inhibitory signaling of cytotoxic T lymphocyte antigen 4 (CTLA-4). CTLA-4 ligation by B7-1 or B7-2 results in inhibition of TCR and CD28 mediated signals (Chen, 2004). Recently discovered B and T lymphocyte attenuator (BTLA) isolated from Th1 cells and expressed mostly by B cells following DCs, Program death-1 (PD1) receptor on lymphocytes and myeloid cells with two counter-receptors B7-H1 (PDL-1) and B7-C (PDL2), respectively, also contribute to tolerance, Figure 12.3.

FIGURE 12.3. The co-signal network model. Co-stimulators (light plates) and co-inhibitors (dark plates) have overlapping but preferential functions in controlling one or more stages of T (and probably) B cell activation, including priming, differentiation, maturation and potentially memory responses. From Chen (2004)

12.4.4.9. Immunologic Memory in Brain

As in any other tissue, the status of post-capillary vein endothelial cells plays a dominant role in penetration of activated lymphocytes into the brain parenchyma (see Chapter 4). Systemic activation of such post-capillary vein endothelial cells by exo- and endotoxins via increased production of $\text{TNF-}\alpha$ and other pro-inflammatory cytokines and up-regulation of adhesion molecules allows lymphocytes to enter perivascular spaces in the meninges and choroids plexus. Neither the meninges nor choroids have an established blood-brain barrier. These two compartments contain potential (macrophages) and actual dendritic cells. Following viral and bacterial infections that might affect APC and induce local immune reactions, memory cells are formed. In healthy individuals at middle age, the CSF contains a very low number of lymphocytes. Over 80% of lymphocytes in CSF are memory T cells ($\text{CD4}^+\text{CD45RO}^+\text{CD27}^+\text{CXCR3}^+$). Continuous recirculation of these cells between blood and the CSF is supported by low levels of P-selectin expression on endothelial cells of the deep stromal veins of the choroid plexus and the bridging meningeal veins. Engelhardt and Ransohoff (2005) reviewed lymphocyte migration in the brain in great detail. These memory cells will persist through human life and respond *in situ* to re-appearing antigen (viral, bacterial, etc.). Even so, the memory recall in the brain is delayed due to the immunosuppressive brain environment and activation of pro-apoptotic T-cells-glia interactions via CD95/CD95L (Fas/FasL), CD30/CD153 , and other probable TNF-family related factors.

12.5. Neuro-Immune Interaction

12.5.1. Innervation of Lymphoid Tissue

In lymphoid organs, similar to blood vessels, sympathetic/noradrenergic and sympathetic/neuropeptide Y (NPY) innervation predominate parasympathetic (cholinergic) innervation and are actually located along the vessels. In the thymus, at the ultra-structural level, noradrenergic fibers are seen in proximity to thymocytes, mast cells and fibroblasts. Catecholaminergic nerve fibers also run in close contact to TECs. Since TECs form the blood-thymus barrier in the outer thymic cortex, these cells may be targets for circulating epinephrine from the adrenal gland or norepinephrine (NE) released from the perivascular nerves. In the spleen the sympathetic nerve fibers are present among cells in the T-dependent area; macrophages and B cells reside in the marginal zone and the marginal sinus, the site of the lymphocyte entry into the spleen. In lymph nodes, noradrenergic fibers supply paracortical and cortical zones (T cell-rich regions) but are absent from nodular regions and germinal centers that contain B cells. The gut, lung and nasal mucosa have the highest intensity of innervation of associated lymphoid tissues. Nerves predominate in T cell zones of lymphoid aggregates where they contain neuropeptides and the sympathetic neurotransmitter NE. Activation of the sympathetic nervous system and also the resting sympathetic nervous tone are important for controlling innate and adaptive immune responses.

12.5.2. Regulation of Immune Cells Activity by Neurotransmitters and Neuropeptides

As was mentioned above, antigen-presenting cells such as thymic TECs and tissue resident macrophages/DCs play an indispensable role in lymphocyte function ranging from programming central tolerance and immunity to support of their effector function and peripheral tolerance. Cells of macrophage/DC origin express functional receptors for NE ($\alpha 1$, $\alpha 2$, $\beta 1$, $\beta 2$), dopamine (D1–5), neuropeptide Y (Y1), opioids (μ , δ , κ), and parasympathetic nicotinic acetylcholine receptors. Complex signaling through these receptors will affect activation status of APCs, expression of co-stimulatory/co-inhibitory molecules and profile of secreted cytokines/chemokines (Elenkov et al., 2000; Tracey, 2002). Signaling through Ach receptors suppresses TNF secretion following the activation of lymphocytes, indicating that the receptors play an anti-inflammatory role.

Macrophages/DCs and lymphocytes express a variety of adrenergic receptors. Increased concentrations of NE or dopamine can modulate T cells polarization toward Th2 profile, stimulate IL-4, IL-5, and IL-13 secretion (Kohm and Sanders, 2001). The same Th2 polarization can be induced by histamine, serotonin, neuropeptides such as substance P, vasoactive intestinal peptide (VIP), pituitary adenylate cyclase-activating polypeptide, calcitonin gene-related peptide, α -melanocyte-stimulating hormone, and leptin (Steinman, 2004).

Summary

After reviewing the development of immune system, it is evident that there is a strong separation between the nervous and immune system based on the absence of professional antigen presenting cells in brain parenchyma and circulating DCs precursors. However, efferent information is actively coming from the brain, but the development of effector reactions is limited by strong central tolerance during education of lymphocyte by TEC expressing brain antigens. The peripheral tolerance is supported by soluble brain antigens filtered through regional lymph nodes and presented by resident DCs in the absence of co-stimulatory signals. The complexity of human adaptive immune responses cannot be reproduced *in vitro*. Each step and hierarchy of interaction of the soluble peptides /proteins with antigen-presenting cells *in situ* and then in draining lymph nodes with different subsets of lymphocytes, as well as, between lymphocytes also can be significantly affected by innervating nervous system. Multiple anatomical and physiological connections exist between the nervous and immune system. Multiple chemical messengers tie these systems together. Thus, these two systems influence each other and interact with each other. Understanding one system may give us insights into the physiology of the other system. The

presented review will help to understand brain immunopathology described in the following chapters.

Review Questions/Problems

1. Briefly summarize the major steps in lymphocyte embryonic development.
2. Briefly summarize the major steps in T lymphocyte development.
3. Briefly summarize the major steps in B lymphocyte development.
4. Briefly summarize the distribution of B cells and their function.
5. Briefly summarize the major steps in helper cells polarization.
6. Briefly describe the development of central tolerance to myelin.
7. Briefly summarize the major factors that limit T cells survival in the brain.
8. Briefly summarize the major steps in adaptive immune responses.
9. Briefly summarize the major steps in helper cells polarization.
10. Briefly summarize the major requirements for B cells differentiation and antibody production.
11. Which of the following cell types exist in thymus?
 - a. thymic epithelial cells
 - b. dendritic cells
 - c. macrophages
 - d. CD3-CD4-CD8- cells
 - e. CD3+CD4+CD8+ cells
 - f. CD3+CD4+ cells
 - g. CD3+ CD8+ cells
 - h. CD3+CD4+CD25+ cells
 - i. all of the above
12. Which cells interaction leads to development of the central tolerance in thymus?
 - a. thymic epithelial cells with CD3-CD4-CD8- cells
 - b. thymic epithelial cells with CD3+CD4-CD8- cells
 - c. dendritic cells with CD3+CD4+CD8- cells
 - d. dendritic cells with CD3+CD4-CD8+ cells
13. Which cells interaction leads to development regulatory T cells in thymus?
 - a. thymic epithelial cells with CD3-CD4-CD8- cells
 - b. thymic epithelial cells with CD3+CD4-CD8- cells
 - c. dendritic cells with CD3+CD4+CD8- cells

- d. thymic epithelial cells with CD3+CD4+CD25- cells
- e. dendritic cells with CD3+CD4-CD8+ cells

14. Which of the following cell types exit thymus?

- a. CD3-CD4-CD8- cells
- b. CD3+CD4+CD8+ cells
- c. CD3+CD4+CD8- cells
- d. CD3+CD4-CD8+ cells
- e. CD3+CD4+CD25- cells
- f. CD3+CD4+CD25+ cells

15. Which of the following interaction affects the survival of T cells in brain?

- a. CD95/CD95L
- b. CD200/CD200L
- c. CD40/CD154

16. Which of the following is NOT considered to be a site of B cells development?

- a. thymus
- b. bone marrow
- c. spleen
- d. liver
- e. lymph node

17. Which of the following macrophage-secreted cytokines is NOT considered to be stimulators of NK cells?

- a. IL-1
- b. IL-10
- c. IL-12
- d. IL-15
- e. IL-18
- f. IL-2

18. Which of the following are the major requirements for lymph node development?

- a. lymphoid organizer
- b. CD45⁺ CD4⁺ CD3⁻ lymphoid tissue inducers
- c. LT β R
- d. LT α 1 β 2
- e. TNF-related activation-induced cytokine (TRANCE)
- f. IL-7/IL-7R
- g. IL-2

19. Which of the following cell types belong to stromal compartment of lymph nodes?

- a. Fibroblastic reticular cells
- b. Sinus endothelial cells
- c. High endothelial cells
- d. T cells
- e. B cells
- f. DCs

20. Which of the following signaling receptor molecules involved in programming of immunologic memory?

- a. CD40
- b. CD27
- c. CD137
- d. ICOS
- e. CD28
- f. all of the above

21. Which of the following co-signaling molecules involved in programming of peripheral tolerance?

- a. CTLA-4
- b. BTLA
- c. PD-1
- d. all of the above

Stem Cells

Hui Peng, Nicholas Whitney, Kang Tang, Myron Toews, and Jialin Zheng

Keywords Neurogenesis; Stem cell; Self-renewal; Proliferation; Differentiation; Microglia; Chemokines; Growth factors; Neurotransmitters

13.1. Introduction

It is now accepted that neurogenesis continues throughout life, contrary to the previously held dogma that no new neurons are produced in the adult human brain. Neurogenesis during development and throughout adult life is a result of the proliferation, migration, and differentiation of neural stem cells (NSC). NSC are cells that can differentiate into all the cells of the central nervous system (CNS) and self-renew while retaining their multipotential capabilities. Numerous factors contribute to the survival, proliferation, migration, and differentiation of NSC. These factors include, but are not limited to, chemokines, growth factors, and neurotransmitters.

Even though it is known that new neurons and supporting cells are produced in the adult, it remains unclear how long these new cells survive and how well they integrate into circuitry of the CNS. Much research has focused on replacing damaged neurons by either transplantation of embryonic, fetal, or adult stem cells or by stimulation of endogenous neural stem cells to undergo growth and differentiation. Both concepts have their advantages as well as difficulties that need to be overcome. Future research into the mechanisms by which neurogenesis is stimulated and new neurons are successfully incorporated into the CNS is imperative for the understanding of development and treatment of neurological injury.

13.2. Stem Cells, Neural Stem Cells, and Neural Progenitor Cells

A stem cell is a special kind of cell that has the unique capacity to continually renew itself and also to give rise to additional specialized cell types. It is now known that stem cells, in various forms, can be obtained from the embryo, fetus, and

adult (Table 13.1). Stem cell plasticity, the ability to differentiate into more than one kind of cell, may vary depending on where the stem cell originates. Although most of what is known about these cells has been learned by studying rodent stem cells, the emphasis of current research is on the utilization of human stem cells for disease therapy.

13.2.1. Embryonic Stem Cell

Human embryonic stem cells were first collected in 1998 by two different research teams. The cells obtained from the inner cell mass of the blastocyst (4- to 5-day embryo) are embryonic stem cells (ESC); in contrast, cells cultured from the primordial germ cells of 5- to 9-week fetuses are embryonic germ cells (EGC). In the laboratory, ES or EG cells can proliferate indefinitely in an undifferentiated state but can also be manipulated to become specialized or partially specialized cell types, a process known as directed differentiation. Both ES and EG cells are pluripotent, meaning they have the potential to develop into more than 200 different known cell types. This class of human stem cells holds the promise of being able to repair or replace cells or tissues that are damaged or destroyed by many of our most devastating diseases and disabilities.

13.2.2. Adult Stem Cell

An adult stem cell is an undifferentiated cell that is found in an otherwise differentiated (specialized) tissue in the adult. It can renew itself for the lifetime of the organism and yield the specialized cell types of the tissue from which it originated. Adult stem cells usually divide to generate progenitor or precursor cells, which then differentiate and develop into mature cell types that have characteristic shapes and specialized functions. Adult stem cells have been found in tissues that develop from all three embryonic germ layers, but these cells are rare. Often they are difficult to identify, isolate, and purify. Most adult stem cells grown in a culture dish are unable to proliferate in an unspecialized state for long periods

TABLE 13.1. Features different stem cell types.

Cell type	Location	Self-renewal capacity	Differential Capacity
Embryonic Stem Cells (ESC)	Inner cell mass of the blastocyst (4- to 5-day embryo)	Infinite	Pluripotent (Can differentiate into every cell of the organism except for the trophoblast)
Embryonic Germ Cells (EGC)	Primordial germ cells of 5- to 9-week fetuses	Infinite	Totipotent (Can differentiate into every cell of the organism)
Adult Stem Cell	Specific niches in adult tissue (Location varies for each tissue/organ)	Infinite	Multipotent (Can differentiate into most cells of the tissue in which they reside. Also, they may have plasticity, which allows them to differentiated into cells of other tissues)
Neural Stem Cell	Embryo: Inner lining of the neuronal tube Fetus: Basal forebrain, cerebral cortex, hippocampus, and spinal cord Adult: Subventricular zone and hippocampal dentate gyrus	Infinite	Multipotent (Can differentiate neurons, astrocytes, and oligodendrocytes)
Neural Progenitor Cell	Fetus: Basal forebrain, cerebral cortex, hippocampus, and spinal cord Adult: Subventricular zone and hippocampal dentate gyrus	Limited (Can self-renew, but only for a limited number of generations)	Multipotent (Can differentiate into at least two cell types of the tissue in which they reside)
Lineage-specific Precursor Cell	Specific niches in adult tissue (Location varies for each tissue or organ)	1. Limited (Can self-renew, but only for a limited number of generations) or 2. Cannot self-renew (It no longer retains the ability to differentiate into more than one cell type), but can amplify in cell number	1. Multipotent (Can differentiate along one specific lineage [e.g., neuronal or astroglial]) or 2. Unipotent (Can only differentiate into one cell type)

of time. The plasticity of adult stem cells appears to be less than that of ES cells; to date there is no isolated population of adult stem cells capable of forming all the kinds of cells of the body.

13.2.3. Neural Stem Cells and Neural Progenitor/Precursor Cell

Neural stem cells (NSCs) are self-renewing, multipotent cells that generate neurons, astrocytes, and oligodendrocytes (Gage, 2000). During embryonic development, neural stem cells (NSCs) arise from generative zones derived from the inner lining of the neural tube that extend from periventricular regions of the telencephalon to the spinal cord within the mammalian central nervous system (CNS). NSCs can be isolated from the embryonic or fetal CNS, including basal forebrain, cerebral cortex, hippocampus, and spinal cord. In the adult nervous system, NSCs can be isolated from neurogenic zones (the subventricular zone and hippocampal dentate gyrus). In addition, more recent evidence suggests that stem cells can be isolated from non-neurogenic areas, e.g., the spinal cord. NSCs can be grown in culture and retain both their pluripotency and ability to self-renew.

Neural progenitor cells (NPC), in contrast, are multipotent and proliferative cells with only limited self-renewal that can differentiate into at least two different cell lineages (“multipoten-

cy,” but not “pluripotency”) (Gage et al., 1995; Weiss et al., 1996; McKay, 1997). Lineage-specific precursors or progenitors are cells restricted to one distinct lineage (e.g., neuronal, astroglial, and oligodendroglial). The term “precursors is used to encompass both stem and progenitor cells” (Emsley et al., 2005) (Figure 13.1).

13.3. Stem Cells and Neurogenesis During Brain Development

Neurogenesis is primarily a process that involves proliferation, migration, differentiation, and survival of neural stem cells (Palmer et al., 1997; Gage, 2000). Multiple factors have been shown to regulate neurogenesis in the developing and adult nervous system including hormones, neurotransmitters, trophic factors, and chemokines (Cameron et al., 1998; Ferguson and Slack, 2003).

13.3.1. Determination and Formation on Neural Tube

The process of developmental neurogenesis begins during embryonic development as the blastula enters a stage called gastrulation. Gastrulation is identified by a small portion of the blastula that undergoes invagination and involution, where a sheet of cells bends inward and migrates underneath the outer layer of

FIGURE 13.1. Characterization of human cortical neural progenitor cells. (A) Cells were isolated from human fetal cortex and culture in NPIM containing EGF, bFGF, and LIF. Cells expressed Nestin, a neural stem/progenitor cell marker. (B-C) After switching to a differentiation medium, NPC were differentiated into neurons (β -tubulin, B) and astrocytes (GFAP, C).

cells. This process forms the endoderm, mesoderm, and ectoderm layers of the embryo. A portion of the mesoderm gives rise to the notochord along the anterior-posterior axis of the embryo. This notochord releases factors that cause primary ectoderm multipotent stem cells to differentiate into more fate-restricted stem cells of the neuroectoderm, forming the neuronal plate. The neuronal plate develops along the dorsal surface with the largest portion, which will form the brain, at the anterior end of the embryo. As the edges of the neuronal plate fold over its center, fuse, and detach from the ectoderm the neuronal plate forms a hollow neural tube with an outer mantle layer and an inner proliferative zone. This neural tube will become the CNS, while a group of cells termed the neural crest on the dorsal side of the neural tube will give rise to the peripheral nervous system.

Upon formation of the neural tube, regionally distinct transcription factors are expressed, designating the configuration of discrete brain regions that will eventually develop into the forebrain, midbrain, cerebellum, hindbrain, and spinal cord (Shimamura et al., 1997; Hatten, 1999). Factors from the microenvironment surrounding neural progenitor cells in the neural tube direct the differentiation of these cells to regionally specific arrays of neurons. These distinct differentiation events include dorsal-ventral polarization in the spinal cord, segmentation in the hindbrain, and lamination in the cerebral cortex (McConnell, 1995).

13.3.2. Neural Stem Cells in CNS Development

The proliferating cells during CNS development reside in the ventricular zone of the neural tube. These cells are a heterogeneous population that exhibit complex patterns of gene expression in both space and time (Temple, 2001). This diversity of gene expression allows differentiation of NSC to astrocytes, oligodendrocytes, and various types of neurons, depending on the signals present in the microenvironment within the developing CNS. As the development of the embryo progresses, multipotent stem cells differentiate into more fate-restricted progenitors, which give rise to macroglial cells and regionally distinct neuron types. These progenitors first give rise to neurons, then to glial cells during embryonic and fetal development, and finally to astrocytes during postnatal growth. Not only is the control of differentiation vital to neurogenesis, but also the regulation of proliferation, migration, and survival of NSC and their differentiated cell progeny. Numerous factors

have been identified to regulate these mechanisms, including growth factors, neurotransmitters, and chemokines; these are discussed in detail in later sections.

13.3.3. Stem Cells in Adult Neurogenesis

It is now accepted that neurogenesis continues throughout life, contrary to the previously held dogma that no new neurons are produced in the adult human brain. Two distinct populations of neural progenitor cells (NPC) have been identified: (1) one in the subventricular zone of the lateral ventricles and (2) another in the dentate gyrus of the hippocampus; other, but possibly less significant, populations of NPC may exist throughout the adult CNS. The physiological role of adult neurogenesis and potential to control it for therapeutic benefit are critical areas of current research for the treatment of neurodegenerative disorders and neural damage.

13.4. Stem Cell Signaling Pathways for Migration, Proliferation, and Differentiation

Neurogenesis includes proliferation, neuronal fate specification of neural progenitors (differentiation), migration, maturation, and functional integration of neuronal progeny into neuronal circuits (Ming and Song, 2005). A full understanding of the molecular mechanisms regulating proliferation, migration, and differentiation of these cells is essential if these cells are to be used for therapeutic applications.

13.4.1. Proliferation

Proliferation and survival of stem cells are important for the maintenance of the neural stem cell pool for neurogenesis. The signals involved include members of the fibroblast growth factor (FGF) family, the transforming growth factor- β (TGF- β) superfamily such as the bone morphogenic proteins (BMPs), the growth and differentiation factors (GDFs), and the Hedgehog family. In addition, many other cues are crucial for neural development.

FGFs constitute a large family of structurally related polypeptide growth factors that signal through receptor tyrosine

kinases. It has been suggested that cyclin D2 (intimately involved in driving cells through the G1 phase of the cell cycle) is an effector of the FGF-dependent maintenance of the caudal stem zone (Lobjois et al., 2004). Receptor-mediated regulation of proliferation involves calcium signaling and the cAMP and PKA pathway. Activation of the Ras/Raf/Mek/Erk pathway is coupled to the cell cycle machinery via interactions with p53 retinoblastoma tumor suppressor protein (Rb) and E2F families of proteins.

Wnts are a large family of highly conserved secreted signaling proteins related to the *Drosophila* wingless protein that regulates cell-to-cell interactions during embryogenesis (Nusse, 2003). In vitro as well as in vivo studies have shown that Wnt signaling is required to expand and maintain neural precursor populations in the brain and the spinal cord. As currently understood, Wnt proteins bind to cell surface receptors of the Frizzled family and act on multiple disparate signaling pathways. Three major pathways have been identified: (i) the Wnt/ β -catenin pathway, also referred to as the canonical Wnt signaling pathway, (ii) the Frizzled/planar cell polarity (Fz/PCP) pathway, and (iii) the Ca^{++} pathway. The details of these signaling pathways have been reviewed recently (Cayuso and Marti, 2005; Ille and Sommer, 2005). For the canonical Wnt signaling pathway, extracellular Wnt molecules bind to Fz seven transmembrane receptors on the cell surface; these Fz receptors are structurally similar to G-protein coupled receptors (GPCRs). Through several cytoplasmic relay components, the signal is transduced to β -catenin, which then enters the nucleus and forms a complex with TCFs (from T-cell factor) to activate transcription of Wnt target genes (Logan and Nusse, 2004).

Sonic hedgehog (Shh) is one of the members of the hedgehog family of secreted proteins required for multiple aspects of development in a wide range of tissues including the CNS (reviewed in Machold et al., 2003). In addition to its fundamental role played in pattern formation of the ventral CNS, the Shh-Gli pathway has been demonstrated to play a major mitogenic role in the development of dorsal brain structures, including the cerebellum, neocortex, and tectum (Dahmane and Ruiz i Altaba, 1999; Wallace, 1999; Wechsler-Reya and Scott, 1999; Dahmane et al., 2001; Pons et al., 2001). Shh mediated proliferation is also required for maintenance of neural stem cells in late development and adult. Shh activity is triggered by the binding of the ligand to its receptor Patched (Ptc), an 11-pass transmembrane receptor. Zinc-finger proteins of the Gli family are known to be transcriptional mediators of Shh-signaling. Within the Shh receiving cell, Gli proteins are regulated in the cytoplasm via multiple distinct molecular mechanisms. The cyclic AMP-dependent protein kinase (PKA) acts as a common negative regulator. Gli repressor forms are generated by PKA-mediated phosphorylation and inhibition of PKA activity releases Gli activated forms. Gli proteins then move to the nucleus where they can activate or repress transcription of specific target genes (Jacob and Briscoe, 2003).

13.4.2. Differentiation

Differentiation is the process by which unspecialized cells (such as a stem cell) become specialized into one of the many highly specialized cells that make up the body. There are two directions of differentiation for neural stem cell: neurogenesis and gliogenesis. The regulation of neurogenesis, as well as the neuronal potential and lineage determination by neural stem cells, has been reviewed (Morrison, 2001). Neurogenic factors such as BMPs promote neurogenesis by inducing the expression of proneural basic helix-loop-helix (bHLH) transcription factors to activate the expression of a cascade of neuronal genes. Moreover, the activity of proneural genes inhibits gliogenesis in the CNS; in contrast, mammalian “hairy and enhancer of split homolog” (HES) gene expression promotes a glial fate. It is likely that other genes also influence multipotent stem cells to become glial precursor cells. Olig1 and Olig2 promote the development of oligodendrocytes. Notch activation acts in neural stem cells as a switch that terminates neurogenesis and initiates gliogenesis, even in the continued presence of neurogenic growth factors (Figure 13.2).

It has been shown that multiple bHLH genes play a critical role in regulation of neural stem cell differentiation (Bertrand et al., 2002; Ross et al., 2003). The activator-type bHLH genes *Mash1*, *Math*, and *Ng2* are expressed by differentiating neurons. These bHLH factors form a heterodimer with a ubiquitously expressed bHLH factor E47 and activate gene expression by binding to the E box, promoting the neuronal subtype specification. bHLH genes promote neuronal subtype specification later in differentiation as well, as reviewed (Kageyama et al., 2005).

While *Mash1*, *Math*, and *Ng2* promote neurogenesis, the repressor-type bHLH genes, including *Hes* genes, regulate maintenance of neural stem cells and promote gliogenesis. There are seven members in the *Hes* family; *Hes1*, *Hes3*, and *Hes5* are highly expressed by neural stem cells. *Hes* factors have a conserved bHLH domain; they form dimers and bind to DNA. The target genes for *Hes* factors include the activator-type bHLH genes such as *Mash1*. *Hes1* represses *Mash1* expression by directly binding to the promoter. The activator-type bHLH factors form a heterodimer with another bHLH activator E47 and promote neuronal differentiation from neural stem cells. *Hes1* forms a nonfunctional heterodimer with E47 and inhibits formation of *Mash1*-E47 heterodimer. Thus, *Hes1* antagonizes *Mash1* by two different mechanisms: repressing the expression at the transcriptional level and inhibiting activity at the protein-protein level.

It has been suggested that Notch signaling is important for maintaining multipotency in some neural stem cells but promotes glial differentiation in others or at different times during development. The Notch signaling pathway is best characterized as mediating cell-cell signaling between adjacent cells. The ligands are members of the Delta and Jagged gene families and the receptors are single-pass transmembrane proteins. Upon ligand binding, the intracellular domain of Notch

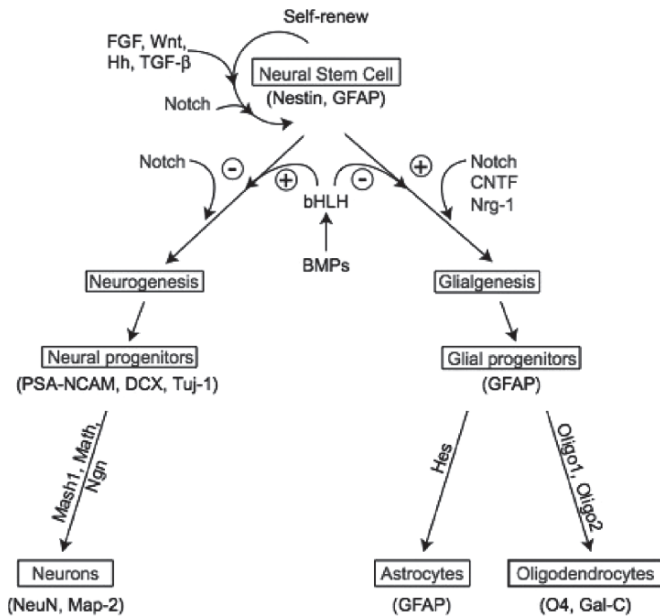

FIGURE 13.2. A proposed mechanism for a select number of factors that regulate self-renew and differentiation of NSC/NPC. Factors that promote self-renewal include but are not limited to fibroblast growth factor (FGF), the transforming growth factor- β (TGF- β), Wnt signaling, and Notch signaling. NSCs are directed toward differentiating along the neuronal lineage by a decrease in Notch signaling and an increase in basic helix-loop-helix (bHLH) transcription factors. As these immature neurons mature they express activator-type bHLH genes *Mash1*, *Math*, and *Ngn*. NSCs are directed toward the glial lineage by a low level of bHLH and a higher level of factors such as Notch, ciliary neurotrophic factor (CNTF), and Nrg-1. As these glial progenitors mature to astrocytes they express *Hes* and as they differentiate into oligodendrocytes they express *Oligo1* and *Oligo2*. Specific cell markers can identify each of these cell types. Nestin and GFAP are expressed by NSC, PSA-NCAM, DCX, and Tuj-1 are expressed by neural progenitors, NeuN and Map-2 are expressed by maturing neurons, GFAP is expressed by glial progenitors and astrocytes, and O4 and Gal-C are expressed by oligodendrocytes.

(NICD) is released from the plasma membrane and translocates into the nucleus, where it converts the CBF1 repressor complex into an activator complex. The NICD/CBF1 activator complex upregulates targets such as the *Hes* and *Herp* (*Hes*-related protein) genes, which block neurogenesis. This is the central mechanism to the inhibition of neuronal differentiation by Notch (Yoon and Gaiano, 2005). The following figure (Figure 13.2) summarizes a proposed mechanism for a select number of factors that regulate differentiation of NSC/NPC.

13.4.3. Migration Signaling

A remarkable feature of the developing CNS is the extensive migration of cells. As specific classes of cells come to reside in specific layers, migration also reflects the programmed control of neuronal fate. Control of these movements is rather complex, involving multiple regulatory genes and several

extracellular molecules. Slit, reelin, and doublecortin may all regulate neuronal cell migration (Nadarajah and Parnavelas, 2002). Slit and its receptor Robos mediate migration of neural progenitor cells crossing the midline in the developing brain (Orgogozo 2004). Doublecortin and reelin regulate cortical neuron migration (Feng and Walsh, 2001; Nadarajah and Parnavelas, 2002). In addition, chemokines, such as SDF-1 α , play an important role for neural progenitor cell migration during development, as discussed in Sect. 13.5.1.

13.5. Chemokines and Neurogenesis

Chemokines constitute a family of structurally related low molecular mass (8–11 kDa) proteins with diverse immune and neural functions. In addition to their well-established roles in the immune system, chemokines play a role in the migration, proliferation, differentiation, and survival of neural stem/progenitor cells. (Refer to the Cytokines and Chemokines Chapter 15.5 regarding chemokine and chemokine receptor classification and signaling pathways).

13.5.1. SDF-1 and its Receptor CXCR4

Studies have shown that chemokine receptors are widely expressed in embryonic and adult neural stem/progenitor cells, including CXCR4, CCR2, CCR5, and CX3CR1 (Ji et al., 2004; Tran et al., 2004; Pen et al., 2004; Wiedera et al., 2004; Ni et al., 2004). CXCR4 is one of the most highly expressed chemokine receptors. Deletion of the gene for the CXCR4 receptor or of its only known ligand, stromal cell-derived factor 1 (SDF-1), results in embryonic lethality. The brains of mouse embryos homozygous for the absence of CXCR4 or SDF-1 have severe abnormalities in the development of the cerebellum (Ma et al., 1998; Zou et al., 1998), hippocampal dentate gyrus (Lu et al., 2001; Bagri et al., 2002), and neocortex (Stumm et al., 2003). In the cerebellum, SDF-1 is highly expressed in the leptomeninges and is the major chemoattractant for external germinal layer cells in the developing cerebellum (Klein et al., 2001; Zhu et al., 2002). In mice lacking SDF-1 or CXCR4, migration of granule cell precursors out of the external germinal layer occurs prematurely, resulting in abnormal development of the cerebellum (Ma et al., 1998). In agreement with a key role for CXCR4, CXCR4 mRNA is expressed at sites of neuronal and progenitor cell migration in the hippocampus at late embryonic and early postnatal ages. The absence of CXCR4 leads to a reduction in the number of dividing cells in the migratory stream and in the dentate gyrus itself; in addition, neurons appear to differentiate prematurely before reaching their target (Lu et al., 2001; Bagri et al., 2002). In the cortex, SDF-1 is highly expressed in the embryonic leptomeninges and is a potent chemoattractant for isolated striatal precursors, while CXCR4 is present in early generated Cajal-Retzius cells of the cortical marginal zone (Stumm et al., 2003). Mice with a null mutation in CXCR4 or SDF-1 show severe disruption of interneuron

placement and proliferation, while the submeningeal positioning of Cajal-Retzius cells remains unaffected (Stumm et al., 2003). In conclusion, SDF-1 likely acts both as a chemoattractant and a mitogenic stimulus for neural stem/progenitor cells in the development of the cerebellum, hippocampus, and neocortex.

SDF-1 may also affect spinal cord development. SDF-1/CXCR4 expression is increased in developing spinal cord progenitors. SDF-1 induced chemotaxis in both neural and glial progenitor cell, suggesting that SDF-1/CXCR4 may affect spinal cord development through modulating progenitor cell migration (Luo et al., 2005).

The expression of SDF-1/CXCR4 in the adult CNS suggests that SDF-1/CXCR4 signaling is also important in adult neurogenesis (Bagri et al., 2002; Tran and Miller, 2005). In the adult, neurogenesis continues in the dentate gyrus. Adult neural progenitor cells in the subgranular zone, which produce granule neurons, express CXCR4 and other chemokine receptors, and granule neurons express SDF-1. The expression of SDF-1 and CXCR4 in adults differs from the embryonic patterns but remains consistent with continued functions in granule cell mitogenesis and/or chemotaxis.

Neural stem cell survival is an imperative issue during neurogenesis. Whether SDF-1-CXCR4 interaction is involved in all three steps of neurogenesis is not clear; however, SDF-1-CXCR4 signaling regulates survival of both neural progenitor cells and oligodendrocyte progenitors in vitro (Krathwohl and Kaiser, 2004; Dziembowska et al., 2005).

13.5.2. Other Chemokines and their Receptors

The role of other chemokines and their receptors in neurogenesis has only recently become realized. For example, it has been suggested that CXCR2 plays a vital role in patterning the developing spinal cord; CXCR2 and its ligand, growth-related oncogene alpha (GRO- α , CXCL1) are crucial in arresting embryonic oligodendrocyte precursor migration (Tsai et al., 2002). Spinal cord oligodendrocytes originate in the ventricular zone and subsequently migrate to white matter, stop, proliferate, and differentiate (Tsai et al., 2002). Without CXCR2 signaling, a widespread dispersal of postnatal precursors has been seen (Tsai et al., 2002). This shows that GRO- α -CXCR2 interaction plays an important role in holding a population of presumptive white matter (Tsai et al., 2002), thus, creating an organized and functional spinal cord. Monocyte chemoattractant protein-1 (MCP-1, CCL2) can also activate the migration capacity of rat-derived neural stem cells. With this in mind, it can be assumed that numerous other chemokines and their receptors will be found to play an important role in regulating NPC function, similar to CXCR4.

13.6. Growth Factors and Neurogenesis

Numerous growth factors regulate neurogenesis in the CNS and are valuable tools in the maintenance and differentiation of NPC in culture. Ciliary neurotrophic factor (CNTF) released by

astrocytes promotes proliferation of NPC (Emsley and Hagg, 2003). Vascular endothelial growth factor (VEGF) in the subventricular zone (SVZ) promotes survival, differentiation, and release of brain-derived neurotrophic factor (BDNF), which will be discussed in detail in Sect. 13.6.2 (Louissaint et al., 2002; Hagg, 2005). Insulin-like growth factor (IGF) produced endogenously in the brain and from circulating blood stimulates proliferation and differentiation of NPC to a neuronal lineage (Anderson et al., 2002). Transforming growth factor (TGF α) produced by astrocytes promotes proliferation by the activation of epidermal growth factor (EGF) receptor (Enwere et al., 2004; Hagg, 2005). Glial-derived neurotrophic factor (GDNF) has been shown to promote survival of dopaminergic neurons in culture (Nakajima et al., 2001). Platelet-derived growth factor (PDGF) may contribute to survival, differentiation, and migration of NPC (Kwon, 2002). Nerve growth factor (NGF) promotes survival and differentiation (Plendl et al., 1999). Although numerous growth factors are significant in neurogenesis, this section will focus on three growth factors: EGF, basic fibroblast growth factor (FGF2) (bFGF), and BDNF.

13.6.1. Epidermal Growth Factor and Basic Fibroblast Growth Factor

EGF and bFGF regulate survival, proliferation, and differentiation of NPC. Regeneration of neurons after ischemic brain injury in rats was significantly increased by infusion of EGF and bFGF (Nakatomi et al., 2002). NPC culture systems use EGF and bFGF to maintain the cell pool by increasing proliferation and survival and by preventing differentiation. After NPC are stimulated to differentiate into neurons, EGF has neurotrophic properties on the newly forming neurons to promote survival. EGF collaborates with sonic hedgehog (SHH) and non-amyloidogenic amyloid precursor protein (APP) to promote proliferation (Machold et al., 2003; Caille et al., 2004; Hagg, 2005; Palma et al., 2005).

13.6.2. Brain-Derived Neurotrophic Factor

Brain-derived neurotrophic factor (BDNF) promotes survival and differentiation of NPC to a neuronal lineage (Mattson et al., 2004; Hagg, 2005). Infusion of BDNF into the brain of rats has been shown to have antidepressant-like properties, as demonstrated by the learned helplessness test and forced swim test (Siuciak et al., 1997). The antidepressant-like activity may be the result of BDNF-stimulated increase in survival and differentiation of NPC to neurons in the hippocampus. This is supported by the finding that BDNF infusion into the lateral ventricle increases the number of newly generated neurons in various regions of the rat brain (Pencea et al., 2001). Neurodegenerative disorders like bacterial meningitis may cause an increase in BDNF levels, which correlates with an increase in neurogenesis (Tauber et al., 2005). These support the idea that BDNF is a crucial factor in the regulation of neurogenesis,

specifically for persuading NPC cultures to differentiate into neurons. BDNF can come from multiple sources, including but not limited to astrocytes, vascular endothelial cells, neurons, and NPC. Other growth factors, hormones, and neurotransmitters may use BDNF as a downstream factor to regulate neurogenesis. BDNF expression in astrocytes can be increased by noradrenaline, serotonin, and glutamate (Zafra et al., 1992; Mattson et al., 2004). Testosterone increases the expression of VEGF, which then stimulates release of BDNF (Palmer et al., 2000; Hagg, 2005). Another regulator of BDNF is nitric oxide production by NPC, which can act in a positive feed back loop with BDNF to shift NPC from proliferation to differentiation (Cheng et al., 2003).

13.7. The Role of Neurotransmitters in the Regulation of Neurogenesis

Neurotransmitters such as acetylcholine (Harrist et al., 2004; Mohapel et al., 2005), dopamine (Baker et al., 2004; Hoglinger et al., 2004; van Kampen and Robertson, 2005), serotonin (Banasr, 2004), norepinephrine (Kulkarni, 2002), GABA (Bolteus and Bordey, 2004; Overstreet Wadiche et al., 2005; Wang et al., 2005), and glutamate (Kitamura et al., 2003; Luk et al., 2003; Brazel et al., 2005), contribute to the regulation of neurogenesis in the dentate gyrus (DG) and the subventricular zone (SVZ) of the lateral ventricles. These neurotransmitters regulate proliferation, differentiation, migration, survival, and synaptic plasticity.

13.7.1. Dopamine in Neurogenesis

Dopamine projections from the midbrain innervate the SVZ and have been shown to promote proliferation and differentiation through the activation of dopamine D2 and D3 receptors (Baker et al., 2004; Hoglinger et al., 2004; Hagg, 2005; van Kampen and Robertson, 2005); however, other evidence suggests that activation of D3 receptors does not affect neurogenesis and D2 receptor activation may inhibit neurogenesis (Baker et al., 2005; Kippin et al., 2005). These apparent contradictions reflect the fact that neurogenesis is complex and is dependent on balance among signals that simulate and inhibit neurogenesis (Hagg, 2005). Specific D3 activation stimulated proliferation and showed preferential differentiation to neuronal phenotype (van Kampen et al., 2004; van Kampen and Robertson, 2005), and dopamine D3 activation has been shown to have neuroprotective effects (Vu et al., 2000; Anderson et al., 2001; Carvey et al., 2001).

13.7.2. Serotonin in Neurogenesis

Serotonin projections innervating the SVZ and DG have been shown to influence proliferation and survival (Simpson et al., 1998; Banasr et al., 2004). Serotonin stimulation of 5-HT_{1a} receptors enhances NPC proliferation and increases levels of BDNF, which promotes survival and stimulates differentia-

tion of NPC to a neuronal lineage (Banasr et al., 2004; Mattson et al., 2004; Hagg, 2005).

13.7.3. Norepinephrine in Neurogenesis

Norepinephrine has been shown to influence proliferation, but it has not been shown to affect survival or differentiation in the DG (Kulkarni et al., 2002). Adrenergic receptors are abundant in the CNS; however, their significance in neurogenesis has not been well established.

13.7.4. GABA in Neurogenesis

Maturing neurons receive GABAergic input for one to two weeks before they form glutamatergic synapses (Overstreet Wadiche et al., 2005). GABA contributes to the stimulation of proliferation, migration, and neurite outgrowth (Owens and Kriegstein, 2002; Bolteus and Bordey, 2004). GABA is essential for the maturation of neurons and formation of functional synapses. GABA's role is not simply the creation of new neurons, but also the formation of functional synapses that ultimately lead to repair or improved neurological function.

13.7.5. Glutamate in Neurogenesis

Glutamate is the primary excitatory neurotransmitter in the mammalian CNS, where it has been shown to mediate synaptic transmission, synaptic plasticity, neuronal toxicity and proliferation, and differentiation of NPC (Dingledine et al., 1999; Arundine and Tymianski, 2004). During many neurodegenerative disorders, extracellular glutamate levels are increased in the CNS. This increased glutamate leads to excitotoxicity of neurons, but some of the negative effects may be counterbalanced by increasing neurogenesis and activation of survival pathways in select cells, including NPC. Glutamate acts on several receptor types, which are classified into "metabotropic" and three "ionotropic" groups: kainate, N-methyl-D-aspartate (NMDA), and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors (Monaghan et al., 1989; Hollmann and Heinemann, 1994; Pin and Duvoisin, 1995). Metabotropic glutamate receptors are GPCRs whose activation leads to release of Ca²⁺ from intracellular stores or inhibition of adenylyl cyclase (Pin and Duvoisin, 1995). Ionotropic receptors are ion channels that open upon binding of glutamate, leading to the influx of sodium and/or calcium and the efflux of potassium, resulting in changes in membrane potential and diverse cellular processes (Arundine and Tymianski, 2004).

NMDA receptor antagonist reduced proliferation of striatal neurons, demonstrating that NMDA receptor activation may induce proliferation (Sadikot et al., 1998; Luk et al., 2003). The metabotropic glutamate receptor subtype mGluR5 is expressed early in development in regions of active proliferation, suggesting that mGluR5 may play a role in proliferation and/or differentiation (Di Giorgi Gerevini et al., 2004).

Numerous studies have shown beneficial effects to neurogenesis by activating and/or potentiating AMPA receptors. By decreasing the rate of desensitization of AMPA receptors, proliferation of NPC increases in rat hippocampus (Bai et al., 2003). Multiple mechanisms have been suggested to explain this AMPA receptor mediated neurogeneration. The increased expression of genes that stimulate proliferation and/or differentiation is one possible method for AMPA-mediated neurogenesis. Activation of AMPA receptors leads to increased expression of immediate early genes, such as: NGFI-A, c-fos, c-jun, and jun-b in oligodendrocyte progenitors (Pende et al., 1994).

Potential of AMPA receptors can also increase BDNF expression in the rat hippocampus, especially in the dentate gyrus (Mackowiak et al., 2002). AMPA receptor activation can lead to upregulation of BDNF in a calcium-dependent and calcium-independent manner. Calcium can bind to calcium response elements on the BDNF promoter, resulting in increased BDNF transcription. Also, AMPA receptors can physically associate with the tyrosine kinase Lyn. Lyn activation through AMPA receptors can stimulate mitogen-activated protein kinases (MAPK), leading to increased BDNF expression (O'Neill et al., 2004). As previously described, BDNF promotes survival and differentiation of NPC to a neuronal lineage (Mattson et al., 2004; Hagg, 2005).

13.7.6. Interaction of Neurotransmitters in Neurogenesis

One factor for the creation of the SVZ and DG niches for NPC and neurogenesis could be the overlap of neurotransmitter systems in these two areas (Simpson et al., 1998; Hagg, 2005). Serotonergic and dopaminergic projections converge almost exclusively over the SVZ. Similarly, serotonergic and norepinephrinergic projections congregate over the DG (Hagg, 2005). None of these neurotransmitters may be sufficient to stimulate neurogenesis on its own; rather, it is the multitude of neurotransmitters, growth factors, and chemokines that combine to create the niche for NPC and to stimulate successful neurogenesis.

13.8. Brain Inflammation and Neurogenesis

Previously, the brain was thought to be an immune-privileged organ. Now it is clear that the brain does respond to peripheral inflammatory stimuli through both neural and humoral afferent signals. The concept that the microglia act as the brain's immune system has also become widely accepted. The inflammatory responses in the brain have different features from those of nonneuronal tissues. Microglia activation and elevated levels of cytokines and

adhesion molecules are hallmarks of CNS inflammation (Matyszak, 1998).

The likely role of immune cells in regulating neurogenesis is of great interest. Their effects may depend on the timing, dynamics, and severity of the inflammation. On the positive side, it has been suggested that the immune system may be protective and even assist regeneration; microglia (Streit, 2002) and macrophages (Rapalino et al., 1998) have been shown to facilitate tissue repair after CNS injury. On the negative side, the immune system may also cause "bystander damage" in the inflamed brain. The limited regeneration capacity and extreme vulnerability of CNS neurons to inflammatory conditions make the inflamed CNS a hostile environment for neurogenesis. Pharmacologic approaches to control neurogenesis and/or neuroinflammation are likely to become important areas of research for treatment of CNS injury and neurodegeneration.

13.8.1. Inflammation can Suppress Neurogenesis

Accumulating evidence suggests that brain inflammation plays an important role in the pathogenesis of chronic neurodegenerative disease such as Alzheimer's disease, Parkinson's disease, and multiple sclerosis (Marchetti and Abbracchio, 2005). Acute brain injury from stroke and status epilepticus is also linked to inflammation. Although it has been reported that these insults trigger increased neurogenesis in the subgranular zone of the dentate gyrus, it has also been shown that newly formed dentate neurons were severely lost, which may be associated with brain inflammation. Arvidsson et al. (2002) showed that more than 80% of new striatal neurons that are generated from the subventricular zone after stroke in rats die within the first week after the insult (Arvidsson et al., 2002). Systemic inflammation triggered by peripheral infection can cause activation of microglia in the brain of Alzheimer's disease patients, leading to aggravation of the cognition decline. Epidemiological studies suggest that patients on long-term anti-inflammatory treatments have a significantly reduced risk of Alzheimer's disease (Zandi and Breitner, 2001).

An invariant feature of damage to the CNS is the migration of microglia to the site of injury and their subsequent activation; however, the specific role of microglia in neurogenesis is still controversial. The activation of microglia can result in either neuroprotective or neurotoxic effects, or both. Previous studies have indicated that microglia are capable of secreting neurotrophic survival factors upon activation (Kim and de Vellis, 2005), and they can direct neural precursor cell migration and differentiation (Kim and de Vellis, 2005). Yet several recent publications (Ekdahl et al., 2003; Monje et al., 2003; Hoehn et al., 2005) report pathogenic roles of microglia on neurogenesis, as well as strengthening the traditional view that immune cells in the CNS have an adverse effect on neurogenesis. In lipopolysaccharide-induced inflammation of the rat CNS, basal hippocampal neurogenesis is strongly impaired and the increased neurogenesis triggered by this brain insult

is also attenuated. This impairment is associated with microglial activation. Activated microglia were localized in close proximity to the newly formed cells, and the impairment of neurogenesis depended on the degree of microglia activation. Systemic administration of the microglial activation inhibitor minocycline effectively restored neurogenesis, presumably by suppressing inflammation without affecting neurogenesis (Ekdahl et al., 2003).

Using a coculture system, Monje et al. (2003) found that activated but not resting microglia decreased the differentiation of neural progenitor cells to approximately half of control levels. Furthermore, in vivo models of acute and chronic inflammation also demonstrated that inflammation itself suppresses neurogenesis. Neurogenesis and activated microglia show a striking negative correlation, and decreased microglial activation by inflammatory blockade with the nonsteroidal anti-inflammatory drug indomethacin likely accounts for part of its restoration of neurogenesis (Monje et al., 2003). Hoehn et al. (2005) also showed indomethacin treatment significantly decreased activated microglia in focal cerebral ischemia in rats. This increased the survival of progenitor cells and allowed a higher fraction to differentiate into oligodendrocytes and neurons. The deleterious effect of activated microglia on neurogenesis is most likely mediated through the action of cytokines, such as IL-1 β or IL-6, TNF α , IFN- γ , NO, and reactive oxygen species; all of these factors can be released from microglia and are neurotoxic in vitro (Hoehn et al., 2005).

When human neural stem cells were transplanted into the ischemic cortex of rats after distal middle cerebral artery occlusion, transplanted stem cells survived robustly in naive and ischemic brains 4 weeks post-transplant. Survival was influenced by proximity of the graft to the stroke lesion and was negatively correlated with the number of IB4-positive inflammatory cells. The negative correlation of cell survival to lesion size and IB4-positive cells suggests that inflammatory cytokines are detrimental to be the transplanted cells, in accordance with other studies (Arvidsson et al., 2002). Given that the magnitude of the inflammatory response and the types of cytokines present change with time after ischemia, these data imply that the timing of stem cell transplant could significantly influence cell survival, with greater survival predicted if cells are transplanted after inflammation has subsided (Kelly et al., 2004).

13.8.2. Proregenerative Role of Microglia and Brain Immunity

Microglia have unique characteristic of being both supportive glia and immunocompetent defense cells. Many observations strongly support a neuroprotective and proregenerative role of microglia in the injured CNS. In the facial nerve axotomy model of neuron-microglia interaction and neural regeneration (Streit, 2002), microglial cells are found to contact the membrane of neurons that will not undergo apoptosis and will eventually regenerate their axons. Their data suggested that microglia may somehow orchestrate the recovery of these

cells by assuming a protective role. Microglia activation after brain injury can also benefit regeneration through the release of neurotrophic molecules and some cytokines (Figure 13.3).

Schwartz and colleagues bring forward a concept of protective autoimmunity (Moalem et al., 1999). Although an uncontrolled immune response impairs neuronal survival and neurogenesis, a local immune response that is properly controlled can support survival and promote recovery. The immune response that causes cell loss under neurodegenerative conditions also blocks neurogenesis in the adult CNS, while the immune response that protects against cell loss also supports neurogenesis (Schwartz, 2003).

The mechanisms by which inflammation regulates neurogenesis remain inconclusive. Recently, investigators have begun to dissect out detrimental aspects of the immune system that may be responsible for unnecessary tissue loss and restrictions on axonal regeneration. Early inhibition of TNF or TGF- β 2 significantly decreases scarring and tissue loss, and can lead to improvement in functional outcome after CNS injury (Brewer et al., 1999; Logan et al., 1999). Further investigation of the roles of individual inflammatory factors, growth factors, and neurotransmitters in neurogenesis will help to shed light on this important research field. Figure 13.3 summarizes a proposed mechanism for the stimulation of neurogenesis during brain injury and neurodegenerative disorders.

13.9. Stem Cell and Neuronal Repair During Brain Injury and Neurodegenerative Disorders

A variety of insults have been shown to be induce neurogenesis within the adult brain (Parent, 2003), either in regions that have known neurogenic activity, or even in regions where neurogenesis normally does not occur (Yamamoto et al., 2001).

Damage induced by mechanical injury, prolonged seizures, trauma or stroke increases dentate gyrus cell proliferation, where a majority of the newly generated cells differentiate into granule neurons (Parent, 2003). It also has been shown that progenitor cells are capable of proliferation and differentiation into mature myelinating oligodendrocytes in models of acute demyelination (Gensert and Goldman, 1997). In various animal models of seizure, such as kainate and pilocarpine models of temporal lobe epilepsy, chemoconvulsant-induced status epilepticus, or electrical kindling models of epileptogenesis, increased dentate granule cell neurogenesis has been observed after stimulation (Parent, 2003). Roles of stem cells in other specific diseases are elaborated below.

13.9.1. Huntington's Disease and Alzheimer's Disease

Increased neurogenesis has been reported in patients with Huntington's disease and Alzheimer's disease (Curtis et al., 2003; Jin et al., 2004). Compared to control patients, Alzheimer's

FIGURE 13.3. A proposed mechanism for the simulation of neurogenesis during brain injury and neurodegenerative disorders. During neuronal injury, neurons produce chemokines, which recruit mononuclear phagocytes (MP) into the brain and to the site of injury. As these MP enter an environment of injury or inflammation, they become activated, subsequently releasing factors that might promote neurogenesis. These factors include but are not limited to neurotrophins, which may act directly to enhance the survival and proliferation of NPCs, and cytokines that might activate astrocytes. These activated astrocytes produce chemokines that could promote the migration of NPCs to the site of injury and they can release neurotrophins that can promote neuronal survival. Once the NPCs receive these migratory and neurotrophic signals, the NPCs can migrate, proliferate, and differentiate into neuronal or astrocyte precursors, which then mature into neurons and astrocytes that may integrate into the CNS circuitry.

disease brains showed increased expression of the immature neuronal marker doublecortin and the early neuronal differentiation protein TUC-4. Expression of doublecortin and TUC-4 was associated with neurons in the dentate gyrus, the physiological destination of these neurons, and in the CA1 region, which is the principal site of hippocampal pathology in Alzheimer's disease. A recent paper (Jin et al., 2004) showed enhanced neurogenesis in Alzheimer's disease transgenic mice, in contrast to previous reports (Haughey et al., 2002; Wen et al., 2002). Similarly, there is a significant increase in cell proliferation in human subependymal layer in response to neurodegeneration of the caudate nucleus of Huntington's patients compared with control brain. These findings indicate that neuron damage or loss can trigger neurogenesis, and this may represent a mechanism directed toward the replacement of dead or damaged neurons.

13.9.2. Cerebral Ischemia

Recent findings in rodents show that cerebral ischemia is another injury that stimulates neurogenesis in adult brain. Yagita et al. (2001) provide evidence that the proliferating cells found after ischemia are neural progenitor cells (Yagita

et al., 2001). Ischemia can lead to the proliferation of newborn cells that migrate into the zone of ischemic injury, differentiate, and express markers of mature striatal neurons (Arvidsson et al., 2002). In general, global cerebral ischemia induces neurogenesis in the dentate gyrus, whereas focal cerebral ischemia additionally increases new neurons in the SVZ (Zhang et al., 2005). Stroke selectively and significantly increases the number of type A and type C cells, which are more actively proliferating neural stem cells. Infusion with the antimitotic agent cytosine-arabino-furanoside to the brain almost completely ablates type A and type C cells in the ischemic subventricular zone, thus indicating that neural stem cells contribute to cerebral ischemia-induced neurogenesis (Chen et al., 2004). In a middle cerebral artery occlusion ischemia model, BrdU labeling was increased in the ipsilateral SVZ and rostral migratory stream, indicating directed migration of neural progenitors toward the infarct area from their sites of origin.

13.9.3. Parkinson's Disease

In contrast to cerebral ischemia, Alzheimer's disease and Huntington's disease, which have clear evidence of increased

neurogenesis, the question of whether adult brain generates new dopamine neurons is still controversial. Using confocal laser scanning microscope, Zhao et al. (2003) found dopaminergic neurons with BrdU-positive nuclei in the substantia nigra (Zhao et al., 2003). But a different conclusion was reported in another study (Frielingsdorf et al., 2004). Kay and Blum (2000) also reported the presence of BrdU-positive proliferative cells in the substantia nigra. Some of cells were identified as microglia, and none of them differentiated into dopaminergic neurons (Kay and Blum, 2000). Another recent study (Yoshimi et al., 2005) revealed lack of neurogenesis of TH-positive neurons from proliferative stem cells in the substantia nigra. These proliferative cells were mainly microglia, but some PSA-positive cells, candidates for newly differentiated young neurons, were present in the substantia nigra and increased in number after dopamine deprivation. Although PSA immunoreactivity is not conclusive evidence of neurogenesis, the results suggests compensatory neuronal differentiation from mitotically silent cells in Parkinson's disease.

13.9.4. Possible Mechanisms of Injury-Induced Neurogenesis

The mechanisms that underlie the injury-induced neurogenesis mostly remain unclear. Growth factors and neurotrophic factors are likely candidates. In the case of forebrain ischemia, it has been shown that expression of bFGF and BDNF increase after injury. Normal neurodevelopment is guided by the spatial and temporal expression of trophic and growth factors, so these factors may represent the brain's attempt to protect injured neurons by activating developmental programs. In addition to protecting neurons, trophic and growth factors have also been shown to stimulate proliferation of adult neural stem cells and to direct their differentiation (Aberg et al., 2000; Pencea et al., 2001).

Activated glial cells are another candidate for directing ischemia-induced neurogenesis. Astrocytes are implicated in the regulation of adult neurogenesis in various settings (Song et al., 2002). Microglia activated during inflammation can be a source of trophic factors and chemokines that influence endogenous stem cell behavior. Endothelial cells are another source of neurotrophic factors, including VEGF, BDNF, bFGF, and chemokines that promote the survival and migration of NSCs. Palmer et al. investigated the relationship of angiogenesis and neurogenesis and referred to the survival coupling of neuroblasts and endothelial cells as the "vascular niche" (Palmer et al., 2000). Treatment with VEGF 24 hours after stroke enhances angiogenesis and neurogenesis, indicating that VEGF plays an important role in brain repair (Zhang et al., 2000).

13.9.5. Functional Significance of Neurogenesis After Injury

While stem cells within the adult brain can be stimulated to replace damaged neurons. Important questions remain:

do these newly formed neurons in the adult brain establish appropriate synaptic connections and are they functionally integrated into the existed network? It is still uncertain to what extent neurogenesis contributes to functional recovery. Newly born neurons can establish synaptic contacts and are electrophysiologically functional (Carlen et al., 2002; van Praag et al., 2002). When neurogenesis was blocked, mice exhibited an impaired performance of a hippocampus-dependent memory task, suggesting that the newly born neurons are involved in the formation of certain types of memories (Shors et al., 2001). Using ionizing radiation to decrease neural regeneration after global ischemia, Raber et al. (2004) demonstrated that reduction of neurogenesis reduces functional recovery (Raber et al., 2004). Consistent with these data, Stilley et al. (2004) reported that transplantation of neuronal cells enhanced cognitive function in patients with basal ganglia stroke (Stilley et al., 2004).

An elaborate study by Ramer et al. (2000) finally documented a functional regeneration of sensory axon (Ramer et al., 2000). Not only were specific behavioral tests corresponding to the regenerated fiber phenotypes used, but they also confirmed their findings by reinjury of the regenerated fibers to demonstrate their capability for participation in functional recovery.

13.10. Neural Stem Cells and their Potential Role in Transplant Therapy for Neurodegenerative Disorders

The use of stem cells to generate replacement tissues for treating neurological diseases is a major focus of stem cell research. Spinal cord injury, multiple sclerosis, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis and Alzheimer's disease are among those diseases for which the concept of replacing destroyed or dysfunctional cells in the brain or spinal cord is a practical goal. The potential of several promising cell types to serve as an effective transplant has been evaluated in terms of the cell's ability to survive, differentiate, and migrate in an inflammatory milieu of the adult CNS (Magnus and Rao, 2005). Many different cell types, including neural stem cells, precursors, and embryonic stem cells, have been suggested as candidate cells for therapy (Rao and Mayer-Proschel, 2000). Several neurological disorders that show some progress in stem cell therapy are discussed below.

13.10.1. Stem Cells for Transplant Therapy

Embryonic stem cells can proliferate indefinitely and under certain condition they can differentiate to neurons and glia in the laboratory. Even though they hold the promise of being able to repair or replace cells or tissues that are damaged or destroyed in neurodegenerative disorders, transplantation of embryonic stem cells is not feasible with current techniques. The lines of

unaltered human embryonic stem cells that exist will not be suitable for direct use in patients. These cells will need to be differentiated or otherwise modified before they can be used clinically. Simply injecting freshly isolated stem cells into the patient would lead to the formation of teratomas, as it occurs when stem cells are injected into mice. Current challenges are to direct the differentiation of embryonic stem cells into specialized cell populations, and also to devise ways to control their development or proliferation once placed in patients.

NSCs isolated from fetal nervous tissue have the potential to differentiate into all types of nervous system cells, including neurons, oligodendrocytes, and astrocytes, so NSCs also have the capacity to replace damaged tissue in both the CNS and PNS. NSCs will restore functional neurons and glia and regenerate injured tissue. It is this characteristic of neural stem cells that makes them a potentially valuable transplantation material in a host of disorders.

Although adult neural stem cells might provide medical solutions that avoid the ethical and legal problems of cloning and fetal stem cell approaches, the limiting factor for the use of adult stem cells in future cell-replacement strategies is that there are insufficient numbers of cells available for transplantation. This is because most adult stem cells that are grown in a culture dish are unable to proliferate in an unspecialized state for long periods of time. In cases where they can be grown under these conditions, they cannot be directed to become specialized as functionally useful cells. New data on the plasticity of adult stem cells may change this situation. A number of studies have suggested that adult stem cells from various organs are plastic, meaning that they can differentiate not only into their original source tissue, but also into cells of unrelated tissue. The limited plasticity of adult stem cells is a major hurdle to overcome before they will be a practical alternative to ES cells, but many believe this feat will be accomplished as study of these cells continues.

13.10.2. Progress in Stem Cell Therapy in Neurological Disorders

13.10.2.1. *Parkinson's Disease*

Among all the CNS disorders, Parkinson's disease (PD) has the longest history of stem cell transplantation therapy. In Parkinson's disease, the loss of dopaminergic neurons in the substantia nigra is the major pathological change; thus, the major transplant therapeutic strategy has been to restore dopaminergic neurons by fetal tissue throughout the 1990s (Lindvall et al., 1990; Mehta et al., 1998; Dunnett and Bjorklund, 1999). However, fetal tissue grafts showed short graft survival and limited integration of the grafts, which appeared to reduce the usefulness of fetal tissue. The use of stem cells has increased recently, since they appear to be far superior to fetal tissue grafts. Several groups have generated highly enriched populations of dopamine neurons from mesencephalic pro-

genitors. Transplantation of expanded mesencephalic precursors resulted in spontaneous transformation into dopaminergic neurons, and functional recovery has been achieved in Parkinsonian rats (Studer et al., 1998; Sawamoto et al., 2001).

Since only limited numbers of NSCs can be purified from the midbrain, embryonic stem cells may be another candidate for transplantation in PD (Storch et al., 2004; Snyder and Olanow, 2005). McKay's group first generated dopaminergic neurons from mouse embryonic stem cells, with greater enrichment achieved by mimicking the oxygen tension of the developing midbrain. When transplanted into 6-OHDA-lesioned rats, embryonic stem cell-derived dopamine neurons showed functional recovery in this dopamine-depleted animal model (Lee et al., 2000; Studer et al., 2000; Kim et al., 2002). Takagi et al. (2005) generated large numbers of dopaminergic neurons from monkey ES cells in vitro (Takagi et al., 2005). Behavioral studies and functional imaging revealed that the transplanted cells functioned as dopaminergic neurons and attenuated MPTP-induced neurological symptoms. This may be one of the most exciting reports from recent research, for the first time showing that a stem cell-based strategy provides clinical benefits in nonhuman primates.

To reach ultimate functional recovery in Parkinson's disease, transplanted dopaminergic neurons must survive, reinnervate the striatum, and integrate into the host nigrostriatal system. While many reports in recent years are encouraging, to date only limited survival of dopamine neurons derived from stem cells has been observed following transplantation. Even in the best case, more than 99% of implanted dopamine neurons died within 14 weeks. This raises the need to develop optimized protocols of transplantation that provide better graft survival; on the other hand, there is also a need to determine the appropriate number of cells required for transplantation. Even though significant progress has been made in stem cell-based strategy of Parkinson's disease in animal models, it is far from certain that these will directly lead to meaningful treatment for human disease (Snyder and Olanow, 2005).

While the current research focuses on dopaminergic neurons, non-dopaminergic degeneration is also an important part of Parkinson's disease pathology. It remains to be established whether it is favorable to implant a pure population of dopaminergic neurons or whether the graft should also contain a specific mix of other neuron types and glial cells to induce maximum symptomatic relief.

13.10.2.2. *Spinal Cord Injury*

Spinal cord injury is associated with the loss of both neurons and glial cells; thus, stem cell-based therapy for reconstituting the injured spinal cord could be used to replace multiple cell types.

The extent of spinal cord injury depends on the severity of the initial trauma as well as the level of subsequent injury. The primary impact of contusion injury triggers a cascade of secondary events including hemorrhage, ischemia, excitotoxicity

and inflammation, which lead to apoptotic neuronal and oligodendroglial death (Beattie et al., 2002). Transplantation will depend on a thorough understanding of the lesion environment and specific deficits associated with the individual injury. To maximize integration of transplanted cells, a variety of strategies such as reducing inflammation, inhibiting apoptosis of transplanted cells by in vitro preconditioning, and modifying the glial scar are being tested (Ramer et al., 2004).

The potential application of neural stem cells for spinal cord injury has been investigated by numerous studies. It has been reported that neural stem cells induced to neuronal differentiation by neurogenin-2 provided significant functional benefit following transplantation after contusion injury (Hofstetter et al., 2005). Further, undifferentiated cells can achieve the regional appropriate phenotype specification in response to local signals in exclusive niches (Gage, 2000).

Embryonic stem cells also have been tested. Myelination in the injured spinal cord by implanted mouse embryonic stem cells was reported (Brustle et al., 1999). A recent study reported that oligodendrocytes derived from human embryonic stem cells were able to myelinate demyelinated foci in spinal cord contusions (Nistor et al., 2005). The discovery of NG2-expressing progenitors within the spinal cord stirred the hope for using endogenous stem cells in spinal cord injury (Horner and Gage, 2000); however, the current incomplete understanding of the neural stem cell niche makes it impossible to control and manipulate, so this ideal approach remains beyond reach.

13.10.2.3. *Multiple Sclerosis*

For multiple sclerosis, it has been demonstrated that spontaneous myelin repair may occur as a physiological response to immune-mediated destruction of the myelin sheath. But the spontaneous remyelination is not robust enough and fails over time (Pluchino et al., 2004). Although it remains unclear which type of cell drives axon re-ensheathment in vivo, endogenous oligodendrocyte progenitor cells are believed to play a role in this process (Bruck et al., 2003). Transplanted oligodendrocyte progenitor cells seemed to be more efficient than endogenous oligodendrocyte progenitor cells in repairing the myelin sheath (Blakemore et al., 2000).

The use of neural stem cells in remyelinating therapy has been explored by many researchers. Pluchino et al. (2003) successfully used adult neural stem cells to promote functional recovery in a multiple sclerosis model. Transplanted neural stem cells showed the ability to selectively reach the demyelinating areas, where they differentiated into axon-ensheathing oligodendrocytes and achieved extensive remyelination (Pluchino et al., 2003).

13.10.2.4. *Other Diseases*

There are relatively fewer reports about the generation of cholinergic neurons, which are the major sites of degenera-

tion in Alzheimer's disease and motor neuron disease. Wu et al. (2002) demonstrate that a "priming" procedure, which involves culturing the fetal human neural stem cells on laminin in the presence of a cocktail of bFGF and heparin in vitro, generates a nearly pure population of neurons after transplantation into adult rat brain. Furthermore, stem cell-derived cholinergic neurons were found following implantation in regions that normally contain many cholinergic neurons, such as the spinal cord and medial septum, but were not seen in regions normally lacking these cells, such as the hippocampus and cortex. In contrast, the human neural stem cells that did not undergo in vitro priming produced primarily glia or undifferentiated cells following implantation (Wu et al., 2002).

Stem cell-based therapy for cerebral ischemia will be more complicated, because the extensive cell death and massive inflammatory response make these brains a more hostile environment for cell grafts. Various sources of cells have been tested for their ability to reconstruct the forebrain and improve function after transplantation in animal models of stroke (Lindvall and Kokaia, 2004). In most cases, only a few grafted cells could survive. Some recent exciting findings in rodents suggest that stroke can induce an increase in neurogenesis; thus, a new therapeutic approach based on self-repair has been brought forth, as discussed in Sect. 13.11.1.

Although stem cell-based strategies have generated some encouraging results, much work is needed to achieve a better understanding of the transplantation efficacy, long-term survival, and functional integration before any future human applications will be feasible.

13.11. Future Directions in Neurogenesis for Neurodegenerative Disorders

Although current research still focuses on cell-based therapies by transplantation of exogenous stem cells or differentiated neurons for neurodegenerative disorders such as Parkinson's disease, Huntington's disease or amyotrophic lateral sclerosis, which all result from a loss of relatively defined phenotypes of cells, accumulating evidence indicates that endogenous neurogenesis may occur as part of an intrinsic brain self-repair process. This raises the possibility of developing therapeutic strategies based on activation of dormant capacities of endogenous neural stem cells.

13.11.1. Endogenous Adult Stem Cells as a Therapeutic Strategy

Recent evidence confirms the widespread occurrence of neural stem cells and the production of new neurons in many parts of adult brain. Although the regeneration of new neurons has been observed only at a very low frequency and can only replace a small fraction of neurons (Fallon et al., 2000; Magavi et al., 2000), these findings encourage work toward

a therapeutic strategy based on neurogenesis, especially in neurodegenerative disease where persistent stimuli for neurogenesis exist or where additional stimulation and regulation are possible. For those neural injuries and neurodegenerative disorders that involve relatively broad areas and many types of neurons, this will be an especially attractive direction. With appropriate manipulation, perhaps many types of neurons that have been considered irreplaceable can be regenerated under the right circumstances (Kruger and Morrison, 2002).

Distinct environmental cues may instruct endogenous progenitors to differentiate into specific neuronal subtypes depending on their locations. Adult stem cells can regenerate specific neuronal subtypes appropriate for the sites of damage. For example, targeted degeneration of corticothalamic neurons in the neocortex and dopaminergic neurons innervating the striatum has been shown to induce regeneration of the same cells types.

The strategy of manipulating endogenous stem cell for repairing relies on finding the appropriate factors and signaling molecules that help the patient's own stem cells survive and grow. Previous studies have shown that exogenous growth factors can increase the rate of neurogenesis in the adult brain and a certain combination of exogenous factors and endogenous stimulation may be necessary for boosting the regeneration of neurons at lesion sites (Weiss et al., 1996). By intraventricular infusion of growth factors, CA1 hippocampal pyramidal neurons that were lost to ischemic injury were remarkable regenerated by endogenous neural progenitor cells. These new neurons not only survived for a long period of time but also established synaptic connections and showed functional contributions by ameliorating deficits in hippocampal-dependent spatial cognition in ischemic rat models (Nakatomi et al., 2002).

Although newly born neurons are able to project over relatively long distances to targets, questions remain about whether and how the projections incorporate into local circuits given the complexity of the adult brain network. Nakatomi et al. (2002) noted that the synapses of newly born neurons appeared to remain immature and exhibited altered electrophysiological properties even 3 months after ischemia. Also, not all incorporation of new cells into the brain circuitry is beneficial (Nakatomi et al., 2002). For example, prolonged seizures lead to the generation of ectopic neurons or abnormal projections in the striatum and hippocampus, so abnormal neurogenesis may even worsen seizure damage by its pro-epileptogenic nature (Parent, 2003).

While a growing number of studies report injury-induced enhancement of neurogenesis, it is clear that endogenous stem cells unable to replace most types of neurons lost to injury. There is no evidence connects neurogenesis with improved functions or slowed disease progression in neurodegenerative disease. Thus, it will not be easy to achieve functional neuronal regeneration and brain reconstruction. For example, although hippocampus is a known site of active neurogenesis throughout adulthood, newly generated cells beyond the dentate gyrus appear to be very limited (Rietze et al., 2000). So it is very important to understand how the brain microenvironment changes as a result of injury,

and how stem cells respond to the spatial and temporal signals presented. The successful development of therapeutic applications based on endogenous neurogenesis will depend on our ability to manage the proliferation, migration, differentiation, and functional integration of recruited cells. Much work is still required to fulfill such a strategy.

13.11.2. Other Potential Therapeutic Value of NSC

The potential therapeutic value of NSCs is greatly enhanced by the basic biology. NSCs are potent vehicles for gene therapy, so NSCs may be useful to carry copies of genes into tissue that will benefit the disease therapy. NSCs are migratory; thus, transplanted NSCs will migrate from the site of delivery to distant areas of active neurogenesis or to the damaged tissue, where they reconstruct both neural networks and glia support. Because NSCs will migrate to distant, multiple, and extensive regions of the nervous system, they may be useful in "global" degeneration, in which all or most of the nervous system is affected. In addition to regenerative capabilities, stem cells may have an immunoregulatory potential. Mesenchymal stem cells have been shown to inhibit effector T-cell activities, reducing autoimmune inflammation of the CNS (Zappia et al., 2005). This immunoregulatory potential of mesenchymal stem cells suggests that NSC may also possess similar properties, but this is an area of research that still remains to be investigated (Uccelli et al., 2006).

Finally, much of the biology of regeneration of nervous system tissue has yet to be discovered. Many of the factors that contribute to regeneration and/or that prevent it remain unknown. NSCs may provide as yet unidentified factors to host tissue, enabling or enhancing regeneration of damaged tissue.

Summary

Neural stem cells, including early stem cells and late progenitor cells, persist throughout life and provide a source for new neurons, astrocytes, and oligodendrocytes to neural tissue in a process called neurogenesis. These cells are critical in neural development and likely contribute to neuronal repair in disorders such as stroke, multiple sclerosis, Parkinson's disease, HIV-1 associated dementia, and brain inflammation. This chapter reviewed the current understanding of neural stem cells, with a particular focus on the chemokines, growth factors, and neurotransmitters that influence the migration, proliferation, and differentiation of neural stem cells during development and in brain disorders.

Acknowledgments. This work was supported in part by research grants by the National Institutes of Health: R01 NS 41858, P20 RR15635, and P01 NS043985 (JZ). We kindly acknowledge Drs. Howard E. Gendelman and Anuja Ghorpade for valuable suggestion and critics of this work.

Shelley Herek, David Erichsen, Alicia Lopez, Ziyuan Duan, Nathan Erdmann, Dongsheng Xu, Li Wu, Clancy McNalley, and Jianxing Zhao provided technical support for this work. Julie Ditter, Robin Taylor, Myhanh Che, Nell Ingraham, and Emile Scoggins provided outstanding administrative support.

Review Questions/Problems

- 1. Which cell type is not likely derived from neural stem/progenitor cells?**
 - a. Neuron
 - b. Monocyte
 - c. Astrocyte
 - d. Oligodendrocyte
- 2. Which of the following is not a necessary process for successful neurogenesis?**
 - a. Proliferation
 - b. Migration
 - c. Differentiation
 - d. Necrosis of stem cell
- 3. Neural tissue is derived from which germ layer?**
 - a. Ectoderm
 - b. Mesoderm
 - c. Endoderm
 - d. None of the above
- 4. What role do basic helix-loop-helix (bHLH) genes Mash1, Math and Ngn have on neurogenesis?**
 - a. Induce differentiation to the glial lineage
 - b. Induce migration of NPC
 - c. Maintain the stem cell pool by regulating self-renewal
 - d. Induce differentiation to the neuronal lineage
- 5. Which receptor does SDF-1 activate to induce migration of NPC?**
 - a. CCR2
 - b. CCR4
 - c. CXCR4
 - d. CX3CR1
- 6. What possible effects could selective serotonin reuptake inhibitors (SSOIs) have on neurogenesis?**
 - a. Increase neurogenesis by enhancing proliferation and survival of NPC
 - b. Increase neurogenesis by inducing migration toward serotonin projections
 - c. Decrease neurogenesis by down-regulating the expression of brain derived neurotrophic factor (BDNF)
 - d. Decrease neurogenesis by inhibiting the proliferation of NPC
- 7. Which cell type releases factor that induce neurogenesis following CNS injury?**
 - a. Astrocytes
 - b. Microglia
 - c. Endothelial cells
 - d. All of the above
- 8. Which is not a complication for embryonic or fetal stem cell transplant therapy?**
 - a. Transplanted cell are recognized by the immune system as foreign and are rejected
 - b. Some cultural ethics oppose the use of embryonic and fetal stem cells
 - c. Transplanted cells preferably differentiate to microglia rather than neurons
 - d. Transplanted embryonic stem cells may form teratomas
- 9. Which is not a complication for an autograft (from one to oneself) transplant of adult stem cells?**
 - a. Limited plasticity of adult stem cells hinders the use of non-neuronal stem cells
 - b. After in vitro culture and transplantation, the immune system recognizes the transplanted cells as foreign and are rejected
 - c. Adult stem cells grown in vitro are usually unable to proliferate in an unspecialized state
 - d. In vitro conditions that allow for adequate proliferation of adult stem cells fail to direct the differentiation to functionally useful cells
- 10. Which is not possible a role (other than neurogenesis) of stem cells in treating CNS disorders?**
 - a. Stem cells can be utilized as vehicles for gene therapy
 - b. Stem cells can inhibit effector T-cell activities, reducing autoimmune inflammation
 - c. Stem cells can actively uptake and degrade neurotoxins
 - d. None of the above
- 11. What are the two criteria that must be fulfilled in order to identify a cell as a “stem cell”?**
- 12. What is the difference between a stem cell and a progenitor cell?**
- 13. Discuss the positive and negative effects inflammation has on neurogenesis.**
- 14. List some of the roles of stromal cell-derived factor 1 (SDF-1) in CNS development and homeostasis.**
- 15. What are the effects of brain-derived neurotrophic factor (BDNF) on NPC?**
- 16. List the processes that a neural stem cell must undergo to become a functional neuron.**
- 17. Discuss the role of Notch signaling in regulating stem cell self-renewal versus differentiation.**

18. Discuss the advantages and shortcomings of embryonic, fetal, and adult stem cells for transplantation therapies.

19. Discuss the benefits and problems associated with therapies using exogenous stem cells as compared to targeting endogenous stem cells to promote neurogenesis.

Keywords Active zone; Central nervous system; Dendrites; Dendritic spine; Neuron; Neurotransmitter; Peripheral nervous system; Postsynaptic density; Synapse

14.1. Introduction

Neurobiology is the study and functional organization of the cells that make up the nervous system. The central nervous system (CNS) begins as a simple neural plate that folds to form a groove and then a tube. Then stem cells within the neural tube are directed toward glia and neurons under the influence of various neural developing signaling processes. It is these cells including, but not limited to, neurons, microglia, astrocytes, endothelial cells, their communication and circuitry, one with the other, that lead to our abilities to sense and respond to the environment, think, ambulate, and behave. Neurobiology is at the very interface of biology and neuroscience but is significantly different from each of the fields. Biology is that of all building blocks of cell organization and function regardless of tissue origin. It is broad and without limits. Neuroscience is by its very integration includes works in computation and cognition that are linked to the clinical disciplines of psychiatry and neurology. Each alone or together relate to cell and system analyses and disease. Nonetheless, the disciplines of neuroscience and biology overlap to generate the field of neurobiology. Here there is a central focus on the cell and its functional outcomes. This chapter seeks to describe the discipline of neurobiology starting from the cell and its function to system organization to function. Such processes underlie both nerve cell communication and function as well as the role glial cells can affect the process overall.

14.2. Neuron

Neurons are the core cell elements of the brain, spinal cord and peripheral nerves that process and transmit information. Neurons are composed of a cell body (soma), dendritic tree (arbor,

where they receive input) and one axon (where they transmit out) that conduct the nerve signal through electrical impulses. Dendrites are cellular extensions with extensive branches and called, a dendritic tree. The chemical synapse occurs only in one direction from the axon. The complexities of the mammalian nervous system are due, in large measure, to neuronal size, shape and functional heterogeneity. Neurons communicate across synapses (the gap between the axon terminal and the dendrites of the receiving cell) through electrochemical signals to and from the brain at up to 200mph. The neuron is without a doubt, the basic anatomical building block of the nervous system. Understanding its functions and that of its organelles opens the discovery of nervous system function itself. The German scientist Heinrich Wilhelm Gottfried von Waldeyer-Hartz coined the word “neuron” in 1891. Subsequently Ramón y Cajal established that the two types of neuronal processes, axons and dendrites, do not interconnect in anastomotic continuity and are therefore independent entities. The many neuronal dendrites receive electrical impulses from the axons of other neurons or receptors and conduct this activity to the neuron’s own axon for transmission to other cells. This basic tenet is called the “neuron doctrine” (Ramón y Cajal, 1995). The cell soma (so called perikaryon) contains the neuron’s nucleus (with DNA and nuclear organelles). The axon, a long extension of the nerve cell, takes information away from the cell body. Bundles of axons are known as nerves or, within the central nervous system (CNS), as nerve tracts or pathways. Myelin coats insulate the axon (except for periodic breaks called nodes of Ranvier), resulting in increased transmission speed along the axon. Myelin is manufactured by Schwann’s cells, and consists of 70–80% lipids (fat) and 20–30% protein. Dendrites branch from the cell body and receive messages from for example axons of other neurons across a synapse. A typical neuron has about 1,000–10,000 synapses (that is, it communicates with 1,000–10,000 other neurons, muscle cells, glands, amongst others).

14.2.1. Axon

A neuron usually only has one axon extending from the soma, but it may have branches distal collaterals. The axon

emerges from the soma and in rare case from a dendrite, and can extend to distant targets up to a meter or more away from the cell body (e.g. motor neurons and corticospinal projection neurons). Microfilaments and microtubules act together to guide and support the growth and differentiation of axons and dendrites. The exploratory activity of growth cones, as they respond to external guidance cues during the formation of axons and dendrites, are driven by actin filaments; whereas, microtubules stabilize the structure of the newly established axon or dendrite (Mitchison and Kirschner, 1988; Smith, 1988b; Gordon-Weeks, 1991; Avila et al., 1994; Tanaka and Sabry, 1995; Heidemann, 1996; Smith et al., 2000).

14.2.2. Dendrites and Dendritic Arbors

Dendrites are extensions from the soma specialized for receiving and processing synaptic inputs. They make connections relatively close to the soma as compared with axons. Dendrites are rarely longer than 1–2 mm, even in the largest neurons. Larger neurons typically have both a larger soma and more extensive dendritic arbors (Figure 14.1). At one extreme, a dendrite connects a single remote target to the rest of the neuron. This is referred to as selective arborization. At the other extreme, dendritic branches can occupy most of the domain of arborization in a space-filling arborization. An example of this type of arborization is the cerebellar Purkinje cell arbor that forms synapses with at least half of the parallel fiber axons that pass through it. Most dendritic arborizations lie between the selective and space-filling varieties and are referred to as sampling arborizations.

14.2.2.1. Intracellular Components of Dendrites

The contents of large proximal dendrites are similar to those of the soma, including the Golgi apparatus and the rough endoplasmic reticulum (RER). These characteristically organelles diminish in number however, with increasing distance

from the soma and decreasing dendrite diameter. The *Smooth endoplasmic reticulum* (SER), which is thought to be involved in the regulation of calcium, unlike the RER is found throughout the dendrites.

Organelles of the early endosomal pathway involved in membrane protein sorting and recycling (*sorting and recycling endosomes*) are common throughout the dendrites. Pits and vesicles representing the initial step in endocytosis are frequently seen in the dendrites. These pits and vesicles have a cytoplasmic coat composed of clathrin (Brodsky, 1988), which gives it a distinctive periodic structure that is also observed on the tips of early endosomes. Clathrin-coated vesicles uncoat less than a minute after their formation from a coated pit (Fine and Ockelford, 1984). For this reason clathrin coated vesicles are only found near their locus of generation within the dendrite.

14.2.2.2. Dendritic Spine

The most common synaptic specializations of dendrites are simple spines. Dendritic spines are protrusions from the dendrite of usually no more than 2 μm , often ending in a bulbous head attached to the dendrite by a narrow stalk or neck. The cytoskeleton of dendrites is composed of microtubules, neurofilaments, and actin microfilaments. In an adult brain, the highest concentrations of actin are associated with the dendritic spines which form the postsynaptic component of most excitatory synapses (Matus et al., 1982; Fifkova, 1985; Kaech et al., 1997). The dendritic spine's actin retains a capacity for dynamic activity which can result in rapid changes in the shape of the dendritic spine (Fischer et al., 1998; Dunaevsky et al., 1999; Halpain, 2000; Lendvai et al., 2000; Matus, 2000). By contrast, the highest concentrations of the microtubule components, including tubulin and the microtubule-associated proteins, occur in the shafts of dendrites (Matus et al., 1981; Bernhardt and Matus, 1982; Burgoyne and Cumming, 1984; De Camilli et al., 1984; Huber and Matus, 1984).

14.2.3. Synapse

Neurons communicate with each other at regions of contiguity called synapses. Foster and Sherrington first coined this term in 1897 (Foster and Sherrington, 1897). The synapse is where the axon terminal of one cell links to a dendrite or soma of another. Neurons may have more than 1000 dendrites that connect to even more cells. Synapses function as excitatory or inhibitory in how they affect neuronal activity. When an action potential engages the axonal termini it opens voltage-gated calcium channels. Calcium then enters which causes neurotransmitters within vesicles to be released into the synaptic cleft that then activates postsynaptic neuronal receptors. In mammals, the majority of synapses are chemical rather than electrical. Substances called neurotransmitters and neuromodulators - either a gas or, more commonly, a liquid, rather than

FIGURE 14.1. The densities of dendritic arbors lie on a continuum of values. Differences in arbor densities reflect differences in connectivity. [Drawings of neurons from (Ramón y Cajal, 1995)].

an uninterrupted electrical signal - convey information from one neuron to another. The presynaptic part contains vesicles with neurotransmitters. There are at least two common ways to categorize the mammalian synapses: (1) the electrical change in the postsynaptic cell (excitatory or inhibitory), and (2) the neurotransmitter used (for example, cholinergic - acetylcholine and catecholaminergic - dopamine). We the latter classification was used. Synapses are typically surrounded by glial cells, which might perform auxiliary roles such as the secretion of neuromodulatory factors, regulation of extracellular ion concentration, and uptake of neurotransmitters (Haydon, 2001). The specific presynaptic plasma membrane region where synaptic vesicles dock and fuse is called "active zone."

14.2.3.1. *Synaptic Adhesion*

The synapse is an intercellular junction whose structural organization shares similarities with other types of junctions such as the immunological synapse or the intercellular junctions of epithelial cells (Dustin and Colman, 2002; Jamora and Fuchs, 2002). Functionally, adhesive interactions between presynaptic and postsynaptic components, more specifically the active zone of presynaptic membrane (see 2.3.2) and postsynaptic density (see 2.3.7), will ensure proximity of release and receptor engagement. Several molecules have been identified in relation to synaptic adhesion, including cadherins (Shapiro and Colman, 1999; Yagi and Takeichi, 2000), protocadherins (Frank and Kemler, 2002), neural cell-adhesion molecule (NCAM), L1, fasciclin II (Davis et al., 1997), nectin (Mizoguchi et al., 2002), neuexins and neuroligin (Missler and Sudhof, 1998), integrins (Chavis and Westbrook, 2001), and syndecans (Hsueh and Sheng, 1999).

14.2.3.2. *Presynaptic Terminal*

A typical presynaptic bouton is a specialized portion of the axon. It is characterized by an active zone, a region where the presynaptic plasma membrane comes into close contact with the postsynaptic plasma membrane and an associated cluster of vesicles (De Camilli et al., 2001). A few synaptic vesicles are adjacent to the active zone and are referred to as docked vesicles. Vesicle exocytosis occurs at the active zone; subsequent endocytic retrieval of vesicular components may occur both at the active zone and in the peri-active zone area (Roos and Kelly, 1999). Vesicle maturation involves acidification of the lumen, loading with the neurotransmitter, association with peripheral membrane proteins needed for exocytosis, and recapture into a vesicle cluster. The vesicle cluster is embedded in an actin-rich area and is generally located next to mitochondria, which provides the energy required for the vesicle cycle and neurotransmitter dynamics and to the endoplasmic reticulum whose function includes the regulation of local cytosolic calcium.

14.2.3.3. *Active Zones*

The active zone is the specialized region of the cortical cytoplasm of the presynaptic nerve terminal that directly faces the synaptic cleft. It has a dense appearance under the electron microscope reflecting the presence of a protein scaffold—the presynaptic grid—within which docked vesicles are nested (Pfenninger et al., 1969). Functionally, the vesicles that are docked, or a subset of them, comprise a readily releasable pool of vesicles (Murthy et al., 2001) (Schikorski and Stevens, 2001). Scaffolding proteins play a role both in recruiting vesicles to the plasma membrane as well as in the regulation of release. This arrangement ensures the exocytotic release of neurotransmitter in close proximity to their postsynaptic receptors and in setting the release process to the appropriate dynamic range.

14.2.3.4. *Exocytosis*

It is now well established that *in vivo* efficient membrane fusion requires the interaction of small cytoplasmically exposed membrane proteins called soluble N-ethylmaleimide sensitive factor (NSF) attachment receptors (SNAREs) (Sollner et al., 1993). For synaptic vesicle exocytosis, the relevant SNAREs are synaptobrevin/ vesicle-associated membrane protein (VAMP) 1 and 2, syntaxin 1, and synaptosome-associated protein of 25,000 daltons (SNAP-25). Synaptobrevins/ VAMPs are localized primarily on synaptic vesicles, while syntaxin and SNAP-25 are localized primarily on the plasma membrane. Fusion is driven by the progressive zipper of vesicle and plasma membrane SNAREs forming a four-helix bundle (Sutton et al., 1998). Although many other proteins appear to play critical roles in synaptic vesicle exocytosis, it seems likely that SNAREs are the minimal machinery required for fusion (Weber et al., 1998). Once assembled, SNARE complexes are disassembled by NSF, which functions in conjunction with SNAP proteins.

14.2.3.5. *Calcium-Triggered Exocytosis*

Synaptic vesicles fuse with the plasma membrane constitutively under resting conditions, but the probability of vesicle fusion is increased dramatically by elevations in cytosolic Ca^{2+} . Synaptotagmin is an integral vesicle membrane protein with two C2 domains that bind Ca^{2+} , SNARE proteins, and phospholipids. A model suggests that Ca^{2+} binding induces the interaction of one or both C2 domains with plasma membrane proteins/lipids to catalyze SNARE-mediated membrane fusion (Fernandez-Chacon and Sudhof, 1999; Chapman, 2002). In addition to synaptotagmin, other proteins with tandem C2 domains are present either on the vesicles [for example, double C2 protein (Doc2) and rabphilin] or at the active zone [for example, Rab3-interacting molecule (RIM) and piccolo] (Rizo and Sudhof, 1998). These together with other calcium-binding proteins within the presynaptic termini, may contribute to Ca^{2+} -sensitivity of exocytosis.

14.2.3.6. Endocytosis: Kiss-and-Run

The concept of synaptic vesicle recycling was conclusively established in the early 1970s (Holtzman et al., 1971; Ceccarelli et al., 1973; Heuser and Reese, 1973), and the role of clathrin-mediated endocytosis in the recycling of synaptic vesicles is now well established. A model of endocytosis referred to as “kiss-and-run” has attracted considerable interest (Ceccarelli et al., 1973; Fesce et al., 1994). In this model, vesicles release neurotransmitter via a transient fusion pore. Newly reformed vesicles may then stay in place, be reloaded, and undergo a new round of exocytosis or may de-dock and allow other vesicles to take their place.

14.2.3.7. Postsynaptic Density

Opposite the active zone on the postsynaptic plasma membrane is an electron dense region referred to as the postsynaptic density (PSD). This membrane structure is thought to be important for both the clustering of postsynaptic receptors and ion channels and for the assembly of the postsynaptic signaling machinery (Hall and Sanes, 1993; Garner and Kindler, 1996). Ultra structural studies have shown that a fine meshwork of filamentous material is assembled at the cytoplasmic face of the active zone and the postsynaptic plasma membrane (Hall and Sanes, 1993; Garner and Kindler, 1996). Electron microscopy also reveals interactions between the PSD and organelles of the dendritic spine. Smooth endoplasmic reticulum cisterns are found in the spine [reviewed by (Fifkova and Morales, 1992)] and in some cases reach the margins of the PSD (Spacek and Harris, 1997). The PSD and spine apparatus appear to be interconnected by actin filaments. However, the actin filaments may be distinct from a PSD core, which contains regulatory components such as α CaMKII (Adam and Matus, 1996). The cytoarchitecture of the spine is thought to be in dynamic flux. Actin concentrations are high in the spine, and its polymerization is negatively controlled by intracellular Ca^{2+} fluxes (reviewed by (Fifkova and Morales, 1992)). The PSD-concentrated molecules include, but are not limited to, ionotropic N-methyl-D-acetate (NMDA) and DL-a-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type of glutamate receptors, the metabotropic glutamate receptors (Nusser et al., 1994), α -actinin-2 (Wyszynski et al., 1997), fodrin (Carlin and Siekevitz, 1983), N-cadherin (Yamagata et al., 1995), calmodulin (Grab et al., 1979), a-calmodulin-dependent protein kinase II (α CamKII) (Kennedy et al., 1983), protein kinase C (PKC) β and γ (Wolf et al., 1986), extracellular signal-regulated kinase 2 (ERK2) (Suzuki et al., 1995), protein kinase A (PKA) (Carr et al., 1992), fyn tyrosine kinase (Suzuki and Okumura-Noji, 1995), TrkB receptor (Wu et al., 1996), and G proteins (Wu et al., 1992). Several PSD-associated molecules are tethered near to or within the PSD via specialized adaptor proteins containing PDZ domains.

14.2.3.8. PDZ Domains

The PDZ domain was originally identified as a common domain found in three structurally similar proteins: PSD-95/SAP90, DLG, and ZO1, which share the Gly-Leu-Gly-Phe sequence motif (Garner and Kindler, 1996; Craven and Brecht, 1998; Hata et al., 1998). Molecular analysis of vertebrate synaptic junctions has revealed that features specific to different types of synapses are achieved through a growing superfamily of proteins containing PDZ domains. The PDZ domain is approximately 90 amino acids in length, and has a high affinity to short peptide sequences located on the C-terminus of the interacting protein. These include, among others, members of the synapse-associated protein (SAP) 90/PSD-95 family [human homologue of the *Drosophila* discs large (hdlg)/SAP97, SAP102 and channel associated protein of synapse-110 (Chapsyn110)/PSD-93], and also CASK, glucocorticoid receptor-interacting protein (GRIP)/ Actin-binding protein (ABP), Synaptic scaffolding molecule (S-SCAM), mammalian homologue of unc-18 (Munc-18) interacting protein 1 (Mint1), and protein interacting with C kinase (PICK1) (Garner and Kindler, 1996; Craven and Brecht, 1998; Hata et al., 1998; Kim and Haganir, 1999). Known interacting molecules of PSD-95 include NMDA receptors, neuroligin, kainate receptor, and guanylate kinase-associated protein (GKAP)/SAP-associated protein (SAPAP) (Kornau et al., 1995; Garcia et al., 1998; Missler et al., 1998; Fujita and Kurachi, 2000). GKAP also interacts with another PDZ-domain containing molecule ProSAP/Shank, which interacts with homer, metabolic glutamate receptors, and cortactin (Boeckers et al., 1999a; Boeckers et al., 1999b; Naisbitt et al., 1999; Tu et al., 1999). Cortactin is an actin-binding molecule, and supports the protein scaffold complex as an architectural anchor on the cytoskeleton. Other known complexes include AMPA receptor subunits GluR2 and GluR3 interaction with PDZ domain of GRIP1 (Dong et al., 1997), GRIP2/ABP (AMPA-receptor binding protein) (Srivastava et al., 1998), and PICK1 (Xia et al., 1999). PDZ-containing molecules also interact with signaling molecules, such as GTPase activating proteins (GAPs) and GDP-GTP exchange factors (GEFs) which regulates the small GTP-binding proteins ras, rac, and rho (Furuyashiki et al., 1999; Alam et al., 1997; Zhang et al., 1999). These signals presumably mediate intracellular dynamics of the PDZ-containing molecular complex, and leads to cytoskeletal movement (such as actin dynamics), complex endocytosis, recycling, and exocytosis.

14.2.4. Axonal Transport

Axon is a polarized extension from cell body, and its plus-end nerve terminal contains presynaptic terminal. The growing axons often contain growth cones at the nerve terminal, mobility of which is critically important for the axonal plasticity. The axon is packed with cargo moving along a unipolar microtubule array either toward the nerve terminal (anterograde transport)

or toward the cell body (retrograde transport). This bidirectional transport process, known as axonal transport, is not fundamentally different from the pathways of macromolecular and membrane traffic that occur in all eukaryotic cells. Anterograde motor machinery is fundamental for the transport of presynaptic molecules in the membrane cargo and mitochondria to the nerve terminal. Retrograde machinery is critically important for neurotrophic signaling, which is mediated by retrograde transport of signaling endosomes, containing neurotrophin-receptor complex, into cell soma. Known neurotrophin/receptor complexes include nerve growth factor (NGF)-TrkA, brain-derived neurotrophic factor (BDNF)/neurotrophin (NTF)-4/NTF-5-TrkB, and NTF-3-TrkC. Such retrograde signaling leads to activation of molecules involved in endocytosis, axonal growth, and cell survival, such as phosphatidylinositol-3-kinase (PI3K), ERK1/2/5, Akt, and cAMP-response element binding protein (CREB) (Heerssen and Segal, 2002).

Membranous organelles are the principal cargo of fast axonal transport. Golgi-derived transport vesicles move anterogradely at maximal rates of $\sim 2\text{--}5\text{ }\mu\text{m/s}$, whereas endocytic vesicles, lysosomes, and autophagosomes move retrogradely at maximal rates of $\sim 1\text{--}3\text{ }\mu\text{m/s}$. One exception to the high duty ratio of membranous organelles is mitochondria (Hollenbeck, 1996). These organelles move less rapidly than most Golgi-derived and endocytic vesicles, forming a kinetically distinct component of axonal transport. Membranous and non-membranous cargoes are all transported along axons by the same underlying mechanism but they move at different rates due to differences in their duty ratio.

Anterograde transport of membrane cargo molecules is mediated by kinesins (such as KIF1), whereas retrograde transport is mediated by dynein. Dynein attached to membrane cargo is inactivated during the anterograde transport. Once membrane cargos travel to the nerve terminal at this “turnaround” zone, cytoplasmic dynein and kinesin become activated and repressed respectively. The exact switching mechanism is currently unknown. A zone for switching the direction of organelle movement also may be created when axonal transport is blocked at a site of nerve injury. After a delay, many vesicles accumulating on the anterograde side of the block reverse their direction and travel back to the cell body (Smith, 1988a), where they may instruct the nucleus to respond to the injury. This reversal may be mediated, at least in part, by the recruitment of additional cytoplasmic dynein onto these vesicles (Li et al., 2000).

14.3. Neuronal Classification

There are different types of neurons. Although all neurons carry electro-chemical nerve signals, they can differ in their structure (the number of processes, or axons, emanating from the cell body) and in their location in the body.

14.3.1. Bipolar Neuron

Bipolar neurons have two processes extending from the cell body (Figure 14.2). Most sensory (or afferent) neurons are this type, carrying messages from the body’s sense receptors (eyes, ears, etc.) to the CNS. Sensory neurons account for 0.9% of all the neurons. Examples of sensory neurons are retinal cells, olfactory epithelium cells, and the cochlear and vestibular ganglia.

14.3.2. Unipolar Neuron (Formally Called Pseudounipolar Neurons)

Actually, unipolar neurons have two axons rather than an axon and dendrite (Figure 14.3). Most interneurons, which form all the neural wiring within the CNS, are of this type. Examples include spinal ganglia, most cranial nerve sensory ganglia, and the trigeminal mesencephalic nucleus. Dorsal root ganglia cells extend one axon centrally toward the spinal cord, and the other axon toward the skin or muscle.

14.3.3. Multipolar Neurons

Multipolar neurons have many processes that extend from the cell body (Figure 14.4). However, each neuron has only one axon. Most motor (or efferent) neurons are this type and account for 9% of all neurons. Multipolar neurons have a diversity of shapes.

Some shapes are so characteristic that those cells are specially named. Examples are:

FIGURE 14.2. A sensory neuron leading a signal from a receptor of the skin through the dendrite to the cell body and subsequently further to the axon (figure used with permission from Biology Mad <http://www.biologymad.com/NervousSystem/nervoussystemintro.htm>).

FIGURE 14.3. Drawing of a unipolar neuron (modified with permission from <http://homepage.psy.utexas.edu/homepage/class/Psy332/Salinas/Cells/sensoryneuron.gif>).

FIGURE 14.4. Drawing of a motor neuron (figure used with permission from Biology Mad <http://www.biologymad.com/NervousSystem/nervoussystemintro.htm>).

Purkinje cell—A single layer of large cell bodies in the cerebellar cortex, between the molecular (left) and granular (right) layers.

Pyramidal cell—named on the basis of the cell body's shape. It is one of the two major neuronal types found in the cerebral cortex. It has a large apical dendrite, which extends vertically from the top of the pyramid, and basal dendrites, which come off horizontally at the base of the pyramid. The axon also typically extends from the base.

Granule cell of dentate gyrus in the hippocampus (a particular region of the cerebral cortex)—dendrites extend from one end of the cell while the axon comes off from the other.

Cortical interneurons—Interneurons in the cortex constitute a rather diverse group of neurons responsible of establishing mostly local circuits in the cortex.

Motor neuron (motoneuron)—Found in the lamina IX of the spinal cord and certain cranial nerve motor nuclei.

14.4. Diversity in Neuronal Transmission

14.4.1. Glutamatergic Neurons

Glutamate (Glu) is the most abundant amino acid in the CNS. About 30% of the total Glu acts as the major excitatory neurotransmitter in the brain. Glu is synthesized in the nerve terminals from two sources: from glucose via the Krebs cycle and from glutamine by the enzyme glutaminase. The production of the neurotransmitter glu is regulated via the enzyme glutaminase. Glu is stored in vesicles and released by a Ca^{2+} dependent mechanism.

Glutamatergic neurons are widely distributed throughout the entire brain. Prominent glutamatergic pathways are the cortico-cortical projections, the connections between thalamus and cortex, and the projections from cortex to striatum (extrapyramidal pathway) and to brainstem/spinal cord (pyramidal pathway). The hippocampus and the cerebellum also contain many glutamatergic neurons. Glutamatergic neurons and NMDA receptors in the hippocampus are important in the creation of long-term potentiation (LTP), a crucial component in the formation of memory. Cortical neurons use Glu as the major excitatory neurotransmitter. Excess stimulation of glutamatergic receptors, as seen in seizures or stroke, can lead to unregulated Ca^{2+} influx and neuronal damage. Decreased

glutamatergic function is thought to be involved in the creation of psychotic symptoms. Phencyclidine and ketamine can induce psychotic symptoms and d-cycloserine or glycine can decrease psychotic symptoms in schizophrenia.

14.4.1.1. Glutamate Receptors

Glu acts at three different types of ionotropic receptors and at a family of G-protein coupled (metabotropic) receptors. Binding of glu to the ionotropic receptors opens an ion channel allowing the influx of Na^{+} and Ca^{2+} into the cell.

14.4.1.1.1. Ionotropic receptors

- NMDA receptors bind glu and N-methyl-D-aspartate. The receptor is comprised of two different subunits: NR1 (seven variants) and NR2 (four variants). The NMDA receptor is highly regulated at several sites. For example, the receptor is virtually ineffective unless a ligand (such as glycine or D-cycloserine) binds to the glycine site of the receptor which is blocked by the binding of ligands [such as MK-801, ketamine, and Phencyclidine (PCP)] to the PCP site.
- AMPA receptors bind glutamate, AMPA, and quisqualic acid.
- Kainate receptors bind glutamate and kainic acid.

14.4.1.2. The Metabotropic Glutamate Receptor Family

The metabotropic receptor family includes at least seven different types of G-protein coupled receptors (mGluR1–7). They are linked to different second messenger systems and lead to the increase of intracellular Ca^{2+} or the decrease of cAMP. The increase of intracellular Ca^{2+} leads to the phosphorylation of target proteins in the cell.

14.4.2. GABAergic Neurons

Gamma-aminobutyric Acid (GABA) is an amino acid with high concentrations in the brain and the spinal cord. It acts as the major inhibitory neurotransmitter in the CNS. Cortical and thalamic GABAergic neurons are crucial for the inhibition of excitatory neurons. GABA is synthesized via decarboxylation of glutamate by the enzyme glutamate decarboxylase (GAD). Two forms of GAD, GAD65 and GAD67, are found in the brain.

The GABA_B receptor is found postsynaptically (causing decreased excitability) as well as presynaptically (leading to decreased neurotransmitter release). GABA is removed from the synapse by a sodium dependent GABA uptake transporter. GABAergic neurons can be divided into two groups: (1) short-ranging neurons (interneurons, local circuit neurons) in the cortex, thalamus, striatum, hippocampus, cerebellum, and spinal cord, and (2) Medium/Long ranging neurons (projection neurons) in: (1) Basal ganglia (caudate/putamen to globus pallidus to thalamus/substantia nigra), (2) Septum to hippocampus, and (3) Substantia nigra to thalamus, superior colliculus.

Benzodiazepines or barbiturates are helpful in the treatment and prevention of seizures, and modulation of GABA_A receptors is beneficial in the treatment of anxiety disorders, insomnia and agitation—most likely due to a general inhibition of neuronal activity.

14.4.2.1. GABA Receptors

GABA acts at three types of receptors: GABA_A, GABA_B, and GABA_C receptors. GABA_A and GABA_C receptors are ionotropic, whereas the GABA_B receptor is a G-protein coupled metabotropic receptor. The GABA_A receptor is a fast responding anion channel that is sensitive to bicuculline and picrotoxin blockage. The receptor-channel complex is comprised of five subunits. Activation leads to the opening of the channel, allowing Cl⁻ to enter the cell, resulting in decreased excitability. Sixteen GABA_A genes encode 5 families of native GABA_A subtypes. Various compounds can bind to several different sites of the receptor. For example, benzodiazepines with high activity at the α1 are associated with sedation whereas those with higher affinity for GABA_A receptors containing α2 and/or α3 subunits have good anti-anxiety activity.

The GABA_C receptor is insensitive to allosteric modulators, such as benzodiazepines and barbiturates. Native responses of the GABA_C receptor type occur in retinal bipolar or horizontal cells across vertebrate species. Although the term “GABA_C receptors” is still being used frequently they have been re-assigned as part of GABA_A receptor family.

The GABA_B receptor is a G-protein coupled receptor with similarity to the metabotropic glutamate receptor that mediates the slow response to GABA. The GABA_B receptor is linked to G_i protein (decreasing cyclic AMP and opening of K⁺ channels) and G_o protein (closing Ca²⁺ channels). The netto effect is prolonged inhibition of the cell. A well-known agonist is baclofen.

14.4.3. Cholinergic Neurons

Acetylcholine (ACh) is known to be a neurotransmitter since the mid 1920s. ACh is synthesized by the enzyme choline acetyltransferase (CHAT) from the precursors acetylCoA and choline. High-affinity and low-affinity transporters pump choline, the rate-limiting factor in the synthesis of ACh, into the cell. ACh is removed from the synapse through hydrolysis into acetylCoA and choline by the enzyme acetylcholinesterase (AChE). Removing ACh from the synapse can be blocked irreversibly by organophosphorous compounds and in a reversible fashion by drugs such as physostigmine and tacrine.

In the peripheral nervous system, ACh is found as the neurotransmitter in the autonomic ganglia, the parasympathetic postganglionic synapse, and the neuromuscular endplate. Cholinergic neurons in the central nervous system are either wide ranging projection neurons or short ranging interneurons in: (1) the basal forebrain (septum, diagonal band, nucleus basalis of Meynert) projects to the entire cortex, the hippocampus,

and the amygdala, (2) the brain stem projects predominantly to the thalamus, and (3) the striatum modulates the activity of GABAergic striatal neurons. ACh modulates attention, novelty seeking, and memory via the basal forebrain projections to the cortex and limbic structures. Alzheimer's disease and anticholinergic delirium are examples of deficit states. Blocking the metabolism of ACh by AChE with drugs such as tacrine and aricept, strengthens cognitive functioning in AD patients. Brainstem cholinergic neurons are essential for the regulation of sleep-wake cycles through projections to the thalamus. Cholinergic interneurons modulate striatal neurons by opposing the effects of dopamine. Increased cholinergic tone in Parkinson's disease and decreased cholinergic tone in patients treated with neuroleptics are examples of imbalances in these two systems in the striatum.

14.4.3.1. Cholinergic Receptors

ACh acts at two different types of cholinergic receptors: Muscarinic and Nicotinic receptors. Muscarinic receptors (1) bind ACh as well as other agonists (muscarine, pilocarpine, bethanecol) and antagonists (atropine, scopolamine). There are at least 5 different types of muscarinic receptors (M1–M5) and all have slow response times. They are coupled to G-proteins and a variety of second messenger systems. When activated, the final effect can be an opening or closing of channels for K⁺, Ca²⁺, or Cl⁻. Presynaptic cholinergic receptors are of the muscarinic or nicotinic type and can modulate the release of several neurotransmitters.

Nicotinic receptors are less abundant than the muscarinic type in the CNS. They bind ACh as well as agonists such as nicotine and antagonists such as d-tubocurarine. The fast acting of the ionotropic nicotinic receptor allows an influx of mainly Na⁺, followed by K⁺, and Ca²⁺, into the cell.

14.4.4. Serotonergic Neurons

Serotonin or 5-hydroxytryptamine (5-HT), a monoamine, is widely distributed in many cells of the body and about 1–2% of the entire serotonin body content is found in the CNS. Serotonin is synthesized by the enzyme amino acid decarboxylase from 5-hydroxytryptophan (which is derived from tryptophan via tryptophan hydroxylase). The rate-limiting step is the production of 5-hydroxytryptophan by tryptophan hydroxylase. Serotonin is removed from the synapse by a high-affinity serotonin uptake site that is capable of transporting serotonin in either direction, depending on the concentration.

Serotonergic neurons are restricted to midline structures of the brainstem. Most serotonergic cells overlap with the distribution of the raphe nuclei in the brainstem (but not all raphe neurons are serotonergic). There are three major groups: (1) a rostral group (B6-8 neurons) projects to the thalamus, hypothalamus, amygdala, striatum, and cortex, (2) The remaining two groups (B1-5 neurons) project to other brainstem neurons, the cerebellum and the spinal cord. Serotonin is linked to many brain functions. For example,

modulation of serotonergic receptors is beneficial (among others) in the treatment of anxiety, depression, obsessive-compulsive disorder, and schizophrenia. Blockade of 5-HT₃ receptors in the area postrema decreases nausea and emesis, and hallucinogens like LSD modulate serotonergic neurons via serotonergic autoreceptors.

14.4.4.1. Serotonin Receptors

Serotonin acts at two different types of receptors: G-protein coupled receptors and an ion-gated channel. All serotonin receptors, except the 5-HT₃ receptor, are G-protein coupled and can be grouped in four groups. The first group: The 5-HT₁ receptors (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C}, 5-HT_{1D}, 5-HT_{1E}, 5-HT_{1F}) are coupled to G proteins (G_i/G_o), and lead to a decrease of cyclic AMP. The 5-HT_{1A} receptor is also directly coupled to a K⁺ channel leading to increased opening of the channel. The 5-HT₁ receptors are the predominant serotonergic autoreceptor. The second group: 5-HT₂ receptors (5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}) are coupled to phospholipase C, which produce inositol triphosphate (IP₃) and diacylglycerol. IP₃ production leads to a variety of intracellular effects, including IP₃-dependent Ca²⁺ flux. The third group: Three receptors (5-HT₄, 5-HT₆, and 5-HT₇) are coupled to Gs and activate adenylate cyclase. The function of the 5-HT_{5A} and 5-HT_{5B} receptors is poorly understood. The fourth group: The 5-HT₃ receptor is the only ligand-gated Na⁺/K⁺ ion channel, resulting in a direct plasma membrane depolarization. It is found in the cortex, hippocampus, and area postrema and is typically localized presynaptically and regulates neurotransmitter release. A well-known antagonist is ondansetron.

14.4.5. Noradrenergic Neurons

Norepinephrine (NE), a catecholamine, was first identified as a neurotransmitter in 1946. In the peripheral nervous system, it is found as a neurotransmitter in the sympathetic postganglionic synapse. NE is synthesized by the enzyme dopamine-β-hydroxylase (DbH) from the precursor dopamine (which is derived from tyrosine via DOPA). The rate-limiting step is the production of DOPA by tyrosine hydroxylase, which can be activated through phosphorylation. NE is removed from the synapse by two mechanisms: (1) catechol-O-methyltransferase (COMT), which degrades intrasynaptic NE, and (2) the norepinephrine transporter (NET), the primary way of removing NE from the synapse. Once internalized, NE can be degraded by the intracellular enzyme monoamine oxidase (MAO).

Nonadrenergic neurons in the central nervous system are restricted to the brainstem, especially at the locus coeruleus (LC). They provide the extensive noradrenergic innervation found in the cortex, hippocampus, thalamus, cerebellum, and spinal cord. The remaining neurons are distributed in the tegmental region. They innervate predominantly the hypothalamus, basal forebrain and spinal cord. LC receives afferents from the sensory systems that monitor the internal and

external environments. The widespread LC efferents lead to an inhibition of spontaneous discharge in the target neurons. Therefore, the LC is thought to be crucial for fine-tuning the attentional matrix of the cortex. Anxiety disorders may be due to perturbations of this system.

14.4.5.1. Adrenergic Receptors

Norepinephrine acts at two different types of noradrenergic receptors in the CNS: α and β adrenergic receptors. α-adrenoceptors can be subdivided into α₁ and α₂ receptors. The α₁-receptors are coupled to phospholipase and located postsynaptically, while the α₂-receptors are coupled to G_i and located primarily presynaptically. Adrenergic β-receptors in the CNS are predominantly of the β₁ subtype. The β₁-receptors are coupled to Gs and lead to an increase of cAMP. cAMP triggers a variety of events mediated by protein kinases, including phosphorylation of the β-receptor itself and regulation of gene expression via phosphorylation of transcription factors.

14.5. Neuronal Degeneration and Regeneration

14.5.1. Wallerian Degeneration

In either the central or peripheral nervous system (CNS or PNS, respectively) of mammals, if an axon of a neuron is focally destroyed (e.g., cut, crushed, frozen, rendered anoxic) the part of the axon disconnected from the cell body, which would be considered 'distal' relative to the lesion, invariably degenerates. This event is called anterograde or Wallerian degeneration. The part of the axon that remains connected to the cell body may degenerate a short distance (e.g. a millimeter or less), but usually it survives at least in the short term. However, there are often reorganizational changes in the cell body of the damaged neuron, denoted by the term chromatolysis. Collectively, all these changes proximal to the lesion site are referred to as retrograde degeneration; some of them may represent reorganization rather than degeneration changes.

14.5.2. Regeneration

After a focal transection of axons in the mammalian CNS, the proximal cut end of the axon, which is still connected to the cell body, may attempt to regrow by sending out sprouts. But axonal regeneration is limited; in practice functional recovery is usually been meager. However, a similar lesion in the mammalian PNS often results in many of those sprouts from the proximal cut end of the axon regrowing to and reinnervating peripheral targets. The regenerated axons may become myelinated too. Characteristically, the population of regenerated, myelinated axons is smaller in diameter and more numerous than in an undamaged nerve. The difference

in regeneration between CNS and PNS is mainly due to the function of Schwann cells in the PNS. Schwann cells provide a “cellular terrain” that is permissive to axonal regrowth. The terrain provided by Schwann cells consists of favorable molecules (e.g., laminin) for growth cone attachment and motility, their intrinsic neurotrophic properties and their myelinating function for regenerated fibers.

14.6. Glia

Glia (microglia, oligodendroglia and astroglia) account for 90% of the total cell numbers in the adult human brain. They have for all but the past half decade been thought to play only scaffolding (surround neurons and hold them in place), nutritional (nutrients and oxygen), and regulatory function (insulate one neuron from another, destroy pathogens, remove debris, and regulate ions and neurotransmitters). Glial cells function to maintain homeostasis, form myelin, and affect neural signal transmission. They are commonly referred to as the “glue” of the nervous system.

A prominent function of glia is to regulate the brain micro-environment and including fluid surrounding neurons and their synapses. With regards to their function glia affect neuron migration both in early ontogeny and development. This is done, in part, through the secretion of growth factors that modify neuronal process growth and differentiation. They are also affect synaptic transmission by regulating clearance of neurotransmitters from the synaptic cleft and by their abilities to modulate presynaptic function. Although glia had been thought to lack chemical synapses or release neurotransmitters this is no longer true. They are no longer considered to be passive bystanders for neural transmission and function. This includes their abilities to prevent toxic accumulations of neurotransmitters such as glutamate as well as release glutamate in response to specific stimulation cues. The most notable differences between neurons and glia rests in their abilities to generate action potentials which neurons have and glia lack. They are also crucial in synaptic plasticity and synaptogenesis.

Astrocytes, the most prominent of glia, play central roles in neuron-to-neuron communication, in neurogenesis and for the developing nervous system. A key advances in neurobiology was the discovery that astroglial can generate neurons not only during development, but also throughout adult life. Few astrocytes maintain their neurogenic potential after development. Although astrocytes can react to brain injury and incite gliosis this rarely affects neurogenesis.

Summary

Neuronal structure has specifically differentiated cellular compartments (axons, dendrites, synapses) for developing interneuronal, neuron-glia, and neuro-immune networks in both the CNS and the PNS. Specific molecules, molecular

complexes, motor machinery, and organelles are developed for different neuronal functions, including synaptic transmission, plasticity, degeneration, and regeneration. There is specific anatomical distribution of neurons with significant diversity in neurotransmitters and their projection to other brain subregions is developmentally regulated. Drugs modulating neurotransmitter receptors and ion channels have been clinically applied for the treatment of neurologic and psychiatric symptoms. An important discovery in neurobiology is that astrocytes can generate neurons beyond development to adult life.

Review Questions/Problems

1. Which states that describe the synaptic vesicle are correct?

- a. In a neuron synaptic vesicles are also called neurotransmitter vesicles
- b. Vesicles store neurotransmitters and are released only during potassium-regulated exocytosis.
- c. Vesicles are not required for propagation of nerve impulses.
- d. ALL of the above

2. All of the following are involved in axonal transport except

- a. Is responsible for movement of mitochondria, lipids, synaptic vesicles, and proteins to and from the neuron.
- b. Axons are up to 10,000 times smaller than the length of the cell body.
- c. Is responsible for moving molecules destined for degradation to lysosomes
- d. Movement toward the synapse is called retrograde transport
- e. b and d

3. Unipolar, bipolar, and multipolar neurons are best described by

- a. Unipolar neuron has a single neurite with different segments that function as superficial receptors or terminals
- b. Multipolar neurons are most common in the nervous system of invertebrates
- c. Neurons can never contain a single axon and dendrite at opposite poles of the cell body
- d. Unipolar neurons make up a major part of the blood brain barrier
- e. All of the above

4. Dysfunction of GABAergic interneurons affects which clinical diseases?

- a. Parkinson's disease
- b. Alzheimer's disease
- c. amyotrophic lateral sclerosis
- d. HIV-1 dementia
- e. Schizophrenia and bi-polar disorders
- f. None of the above

5. Which of the following is true to describe Wallerian Degeneration?

- If a nerve fiber is crushed, the part proximal to the injury (i.e. the part of the axon that is connected from the neuron's nucleus) will degenerate
- Target tissues of the nerve (typically an innervated muscle) never atrophies
- Wallerian degeneration is named after Augustus Volney Waller who first described it in 1850, in the Zebra fish
- None of the above

Cytokines and Chemokines

Yunlong Huang, Nathan Erdmann, Terry D. Hexum, and Jialin Zheng

Keywords Chemokine; Cytokine; Growth factor; HIV-1 associated dementia; Alzheimer's disease; Multiple sclerosis; Inflammation; Chemotaxis

15.1. Introduction

Chemokines, cytokines, and growth factors are signaling molecules that play a crucial role in the coordination of immune responses throughout the body and communication between the immune system and the CNS. Consequently, dysregulation of chemokines, cytokines, and growth factors may facilitate the development of several central nervous system (CNS) diseases. For example, HIV-1 associated dementia (HAD), Alzheimer's disease (AD), and multiple sclerosis (MS) share certain characteristics in their pathogenesis, which include activated macrophage/microglia, production of high levels of proinflammatory cytokines, and impairment of neuronal function. The relationship between disturbances of the immune response and the impairment of neuronal function is the subject of intense investigation. This chapter provides an overview of chemokines, cytokines, and growth factors and their roles in various pathological conditions. Understanding the involvement of chemokines, cytokines, and growth factors in the pathogenesis of CNS diseases may potentially provide the opportunity to identify particular therapeutic targets for the treatment of neurodegenerative disorders.

15.1.1. Classification of Cytokines, Chemokines, and Growth Factors

Cytokines are regulatory proteins secreted primarily by white blood cells but also by a variety of other cells in the body; their functions include numerous effects on cells of the immune system and inflammatory processes (Vilcek, 2003). Most cytokines are single polypeptide chains, although they may form multimers in biological fluids. As an exceptionally large and diverse group of factors, cytokines

are very difficult to classify. While many factors share structural similarities or have functional homologues, most generalizations are riddled with exceptions. Similarly, the term "growth factors," used in this chapter, also refers to a broad range of structurally diverse molecular families and individual proteins.

15.1.2. Cytokine Families

Cytokines can be grouped into families based upon their structural homology or structural homology of their receptors. Below, is an effort to group cytokines and their families based on the structural homology of their receptors. This classification helps provide a foundation for thinking about these factors and their role in the brain.

15.1.2.1. Type I Cytokine Family

Despite minimal amino acid sequence homology, type I cytokines and receptors share a similar three-dimensional structure consisting of an extracellular region containing four α helices, a characteristic motif of type I receptors. Members of this family include interleukin-2 (IL-2), IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-12, granulocyte-colony stimulating factor (G-CSF), and granulocyte macrophage-colony stimulating factor (GM-CSF). Among them IL-2, IL-3, IL-4, IL-7 are T cell growth factors; IL-2, IL-6, IL-12 are pro-inflammatory cytokines; and G-CSF and GM-CSF are hematopoietic cytokines important for survival and differentiation of hematopoietic lineages. Interestingly, although belonging to the same family, IL-2 is a Th1 cytokine but IL-4 and IL-5 are Th2 cytokines.

15.1.2.2. Type II Cytokine Family

Type II cytokines include IL-10, IL-19, IL-20, IL-22, and interferons (IFN- α , - β , - ϵ , - κ , - ω , - δ , - τ and - γ). Functions of this group include induction of cellular antiviral states, modulation of inflammatory responses, inhibition or

stimulation of cell growth, and production or inhibition of apoptosis, as well as affecting many immune mechanisms (Renauld, 2003; Pestka et al., 2004). Notably, IL-10 is a potent anti-inflammatory, immunomodulatory cytokine. The IFN system is an important contributor to innate immunity with IFN- γ serving as a potent pro-inflammatory cytokine. The type II cytokine family is also comprised of both Th1 and Th2 cytokines; IFN- γ is a Th1 cytokine while IL-10 is a Th2 cytokine.

15.1.2.3. *TNF Family*

TNF family is comprised of at least 19 type II transmembrane proteins that have partial homology in their extracellular domains. Members of this superfamily include TNF- α , TNF- β , Fas ligand (FasL), CD40 ligand (CD40L), and TNF-related apoptosis-inducing ligand (TRAIL). Members of the TNF family are known for their apoptosis-inducing ability, though they have additional biological effects. TNF- α is an inflammatory Th1 cytokine released during infection. CD40L is a strong activator of macrophage, while FasL and TRAIL modulate immune responses through the induction of apoptosis. TNF family cytokines also have been suggested to be involved in destructive effects toward tissue in many disease settings.

15.1.2.4. *IL-1 Family*

The IL-1 family is also called the immunoglobulin superfamily. The IL-1R family includes both transmembrane and soluble proteins with an immunoglobulin-like structure. There are four primary members of the IL-1 family: IL-1 α , IL-1 β , IL-18, and IL-1Ra. IL-1 ligands (IL-1 α and IL-1 β , collectively referred to as IL-1) are potent pro-inflammatory cytokines that induce genes associated with inflammation and autoimmune disease. IL-1Ra, on the other hand, is the specific receptor antagonist for IL-1 α and IL-1 β but not for IL-18.

15.1.2.5. *TGF- β Family*

Transforming Growth Factor Beta (TGF- β) is the prototypical member of this family, but at least 50 proteins are classified as TGF- β members including activins, inhibins, bone morphogenetic proteins (BMPs), and glial cell line-derived neurotrophic factor (GDNF). The receptors of TGF- β family have characteristic cysteine-rich extracellular domains, kinase domains, GS domains, and a serine/threonine-rich tail (type II receptors). TGF- β has numerous functions including regulation of neuronal survival, orchestration of repair processes, as well as anti-inflammatory properties.

15.1.3. Important Sub-families of Cytokines and Growth Factors

The designation of five cytokine families based upon receptor structural homology is rather vague. Cytokines within each structural family have further diversity in function; hence,

smaller groups of cytokines can be designated by the formation of more function-related sub-families. Due to their proliferative and/or differentiative effects, a group of cytokines are collected from different families and referred to as neurotrophic factors, e.g., nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF). Growth factors are known for their ability to enhance cell proliferation and growth. Some growth factors are included in the cytokine family, e.g., platelet-derived growth factor (PDGF). However, other growth factors are classified into different families, e.g., epidermal growth factor (EGF) and fibroblast growth factor (FGF).

15.1.3.1. *Neurotrophic Factor Families*

The neurotrophin family includes NGF, BDNF, neurotrophin-3 (NT-3), NT-4/5, and NT-6. All neurotrophins are capable of binding to the p75 receptor; each neurotrophin also binds to a specific Trk receptor. Trk is the receptor for NGF; TrkB is the receptor for BDNF and NT-4, while TrkC is the receptor for NT-3. Neurotrophins secreted by cells protect neurons from apoptosis (Korsching, 1993; Lewin and Barde, 1996). Similarly, ciliary neurotrophic factor (CNTF), a structurally related type I cytokine and GDNF, structurally related to TGF- β , each constitute a sub-family of neurotrophic factors.

15.1.3.2. *Growth Factor Families*

Growth factors are comprised of multiple families, each with unique functions. One family includes vascular endothelial growth factor (VEGF) and PDGF which are potent mitogenic and angiogenic factors with critical roles in embryonic development, wound healing, and the integrity of the blood brain barrier (BBB). Epidermal growth factor (EGF) family members include EGF, neuregulins, amphiregulin, and betacellulin. The EGF family members mediate their growth and proliferative effects on cells of both mesodermal and ectodermal origin. Insulin-like growth factor (IGF)-I and IGF-II belong to the family of insulin-like growth factors that are structurally homologous to proinsulin. IGF-1 has a much higher growth-promoting activity than insulin and is highly expressed in all cell types and tissues. IGF-2 is expressed in embryonic tissues and is related to development. The FGF family is another group of cytokines involved in many aspects of development including cell proliferation, growth, and differentiation. They act on several cell types to regulate angiogenesis, cell growth, pattern formation, embryonic development, metabolic regulation, cell migration, neurotrophic effects, and tissue repair.

15.1.4. Structure and Classification of Chemokines and Their Receptors

First discovered in 1987 (Walz et al., 1987; Yoshimura et al., 1987), chemokines include a group of secreted proteins within the family of cytokines that by definition relate to the induction of migration. These “**chemotactic cytokines**” are produced by and target a wide variety of cells, but

primarily address leukocyte chemoattraction and trafficking of immune cells to locations throughout the body via a gradient. There are two general categories of biological activity for chemokines, the maintenance of homeostasis and the induction of inflammation (Moser and Loetscher, 2001). Homeostatic chemokines are involved in roles such as immune surveillance and the navigation of cells through hematopoiesis, and are typically expressed constitutively. Inflammatory chemokines are produced in states of infection or following an inflammatory stimulus, and by targeting cells of the innate and adaptive immune system, facilitate an immune response.

Chemokine activity is mediated by binding a family of seven transmembrane G-protein coupled receptors (GPCR). Chemokine receptors are classified into four families based on the number and position of the N-terminal-conserved cysteine residues within the receptor binding domain. Those receptors with two cysteine residues separated by one amino acid are categorized as α -chemokine receptors (such as CXCR2 and CXCR4); whereas those with two cysteines immediately next to each other are designated as β -chemokine receptors (such as CCR5, CCR4, CCR3 and CCR2). The only γ -chemokine receptor to this point has a single cysteine residue (XCR1) and δ -chemokine receptors have three amino acids separating the two cysteine residues (CX3CR1) (Gabuzda et al., 1998; Hesselgesser and Horuk, 1999; Klein et al., 1999; Miller and Meucci, 1999; van der Meer et al., 2000; Cotter et al., 2002). GPCRs interact with and signal through heterotrimeric guanine-nucleotide-binding regulatory proteins (G-proteins). Upon stimulation by a ligand, GPCRs undergo a conformational change that leads to activation of the G-protein by GDP-GTP exchange, followed by uncoupling of the G-protein from the receptor. Upon activation, G-proteins trigger a cascade of signaling events that regulate various cellular functions (Devi, 2000).

15.1.4.1. CXC Chemokines

CXC chemokines are further separated into two groups based upon the presence or absence of a specific three amino acid sequence found adjacent to the CXC. The Glu-Leu-Arg residues constitute the ELR motif, and if present, the CXC chemokine is considered to be ELR(+). The general function of ELR(+) chemokines revolves around neutrophils, inducing chemotaxis and promoting angiogenesis (Strieter et al., 1995). Chemokines in this group include CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8, and CXCL15; unlike ELR(-) members, these factors interact primarily with neutrophils via CXCR1 and CXCR2 receptors. In contrast, ELR(-) chemokines attract lymphocytes and monocytes with little affinity for neutrophils. This subgroup including CXCL4, CXCL9, CXCL10, CXCL11, CXCL12, CXCL13, CXCL14 and CXCL16, has a wider variety of activities, but generally have angiostatic properties and induce chemotaxis in mononuclear cells.

15.1.4.2. CC Chemokines

CC chemokines target primarily mononuclear cells and serve in both homeostatic and inflammatory capacities. The family can be divided into functional groups including allergenic, pro-inflammatory, developmental and homeostatic. The developmental and homeostatic factors are, as expected, constitutively produced, whereas the other groups contain largely inducible signals. Allergenic CC chemokines target eosinophils, basophils and mast cells and are potent attractors and stimulants of histamine release. Inflammatory chemokines are also inducible and can amplify inflammation through the recruitment of effector cells.

15.1.4.3. CX3CL1

CX3CL1 (Fractalkine, FKN) is the lone member of the CX3C subfamily with three intervening residues between the first two cysteines. FKN, the ligand for CX3CR1, is a 373-amino acid, multi-domain molecule found in a wide variety of tissues, including liver, intestine, kidney, and brain. Structural components of FKN include a 76-amino acid chemokine domain (CD) at the N-terminus, which is important in the binding, adhesion, and activation of its target cells (Mizoue et al., 1999; Goda et al., 2000; Haskell et al., 2000; Harrison et al., 2001; Mizoue et al., 2001). FKN also has an 18-amino acid stretch of hydrophobic residues that spans the cell membrane, and an extended carboxyl-terminus that anchors it to the cell surface (Hoover et al., 2000; Cook et al., 2001; Lucas et al., 2001), thus allowing a membrane form as well as a shed soluble form targeting monocytes and T cells (Bazan et al., 1997).

15.1.4.4. XCL1

The final chemokine member is XCL1 (Lymphotactin), the only representative of the C family. This chemokine targets CD4 + and CD8 + lymphocytes, but does not act on monocytes, and binds a unique receptor, XCR1. Although having some homology to ligands CCL3 and CCL8, XCL1 lacks the first and third cysteines characteristic of the CC and CXC chemokines.

All of the above families are imperative for homeostatic functions as well as the orchestration of response to pathogenic insult by the immune system. As investigations carry on, this large family will likely see the emergence of additional cytokines and growth factors, and the family and sub-families of cytokine, growth factor, or chemokine receptors will continue to evolve and expand.

15.2. Cytokines and Growth Factors in the CNS

The view of neuroimmunology has evolved from the dogma that regarded the CNS as an immune privileged site to a view of significant CNS-immune system interactions. Cytokines and growth factors are important to the brain's immune

function, serving to traffic leukocytes, maintain immune surveillance, and recruit inflammatory factors. In the normal physiological state immune cells readily cross the blood brain barrier (BBB) and traverse the healthy CNS (Hickey, 1999). As discussed in Chap. 38, CNS inflammation is unique due to the presence of the BBB. A restricted inflammatory process in the CNS is initiated upon encountering foreign antigen, inducing the production of recruitment factors (Irani, 1998). Upon recruitment, monocytes and lymphocytes cross through the BBB to mount immune responses in the CNS. Recruitment is dependent upon the presence of chemotactic factors produced within the CNS that facilitate the crossing of the BBB. This inflammatory state is highly regulated, usually self-limited, and differs from the inflammation in peripheral tissue sites. The threshold to initiate immune responses against antigens in CNS is much higher than that in periphery (Matyszak, 1998; Perry, 1998). Avoidance of uncontrolled activation, release of toxic factors, edema and other effects of robust inflammation are crucial to the maintenance of the vulnerable microenvironment in the CNS. Cytokines and their receptors detectable in brain tissues or neuronal and glial cultures under pathophysiological conditions are summarized in Table 15.1.

CNS-immune system interactions are regulated by cytokines, chemokines, and growth factors. Immune cells, after

stimulation by pathogens or abnormal cells, release cytokines, which then interact with immunosensory tissues. Immunosensory structures respond to cytokines, then activate brain neuro-immune circuits responsible for the induction of the defensive response. In the brain, microglia are the resident macrophage and present antigen, orchestrating the innate immune responses. Astrocytes have also occasionally been postulated to have a role in antigen-presentation to CD4⁺ T cells in the CNS. Other resident cells, such as neurons or oligodendrocytes, are all capable of recruiting immune cells, modulating the immune response through cytokines, chemokines, or growth factors. In addition, neurons may also modulate the antigen-presenting function of microglia. For example, neuronal production of neurotrophins also suppresses IFN- γ induced MHC class II expression (Neumann et al., 1998).

Disease states within the CNS can lead to dysregulation of the inflammatory process. In acute insults such as ischemia or traumatic injuries, evidence suggests cytokines IL-1 and IL-6 are rapidly induced. These pro-inflammatory molecules have been reported to cause neuronal death through different mechanisms. In general, if present for extended periods of time, IL-1 exacerbates acute neurodegeneration through induction of fever, upregulation of neurotoxic molecules such as arachidonic acid, or promoting leukocytes transmigration (Tarkowski

TGF- β	Macrophage/microglia, Astrocytes, Neurons	Macrophage/microglia Astrocytes, Neurons	(Logan and Berry, 1993; van der Wal et al., 1993; Perrella et al., 2001)

et al., 1995). Chemokines such as MCP-1 also elevate in acute insults and promote inflammation through recruitment of leukocytes critical to propagate tissue damage (Hausmann et al., 1998). In states of prolonged inflammation, continual activation and recruitment of effector cells may establish a positive feedback loop that perpetuates inflammatory processes and can ultimately lead to neuronal injury and dropout. Similar yet distinct processes occur in multiple CNS disorders such as MS, HAD, and AD. One underlying similarity in each disease state is the cytokine driven inflammatory response (see Figure 15.1). Numerous studies have demonstrated that microglia/macrophage and astrocytes are major sources of inflammatory mediators, including TNF- α and IL-1 β , IL-10, and nitric oxide (NO). These mediators initiate or regulate inflammatory processes in the CNS (Aloisi, 2001; Dong and Benveniste, 2001; Hanisch, 2002). In addition to the beneficial effects that glia have in initiating protective immune responses in the CNS, these cells have been implicated in contributing to tissue damage when chronically and/or pathologically activated. For example, many reports demonstrate that activated microglia may exacerbate AD and MS, as described later in this chapter, through secretion of a battery of inflammatory cytokines and cytotoxic agents (Meda et al., 1995; Renno et al., 1995; Benveniste, 1997).

15.3. Molecular Mechanisms of Cytokines, Growth Factors, and Chemokines Activity and Signaling

Multiple signaling pathways have been observed for various cytokines. We will first discuss the molecular signaling of neuronal survival and cell death to better explain the molecular mechanisms involved in cytokine-induced neurodegeneration.

The signaling events leading to apoptosis can be divided into two distinct pathways, involving either the mitochondria (*intrinsic*) or death receptors (*extrinsic*) (for reviews, see Green and Reed, 1998; Green, 2003). The mitochondrial pathway is initiated through various stress signals that impair the mitochondrial membrane integrity. BCL-2 family proteins, including the anti-apoptotic members, i.e., BCL-2 and BCL-XL, and pro-apoptotic members, i.e., Bax, Bak, play a critical role in this pathway (Gross et al., 1999; Wang, 2001; Green, 2003; Danial and Korsmeyer, 2004). The BH3-only BCL-2 family proteins, such as Bid, Bad, Bim, and PUMA, serve as sentinels to these stress signals. Once activated, BH3-only proteins translocate to the outer membrane of mitochondria, where they trigger the oligomerization and activation of both Bax and Bak. In turn, Bax and Bak cause the release of cytochrome c (cyto c) and other apoptogenic factors, including second mitochondrial-derived activator of caspase (SMAC), Htr2, apoptosis inducing factor (AIF), and endonuclease G (EndoG) (Green and Reed, 1998). Cyto c then binds the cytosolic adaptor protein, Apaf-1, mediating the formation of the apoptosis complex "apoptosome." Such

complexes lead to the activation of caspase-9, which further processes and activates the effector caspases, pro-caspase-3, 6, or 7. Effector caspases then cleave death substrates and complete apoptosis. The death receptor pathway is initiated through interaction with death receptors and the recruitment of cytoplasmic proteins to specific regions in the intracellular domains of these receptors. The receptor adaptor protein complex then binds pro-caspase-8 and forms a death-inducing signaling complex (DISC) that subsequently releases active caspase-8. Active caspase-8 then activates a caspase cascade and eventually leads to apoptosis of the cell. Many cytokines influence the apoptotic pathways through various receptors and intracellular mediators. Members of TNF superfamily, such as TNF- α , TRAIL, or Fas ligand are able to interact directly with death receptors on neurons initiating neuronal apoptosis through activation of the caspase cascade.

In contrast to the apoptotic pathway, some cytokines and growth factors are able to induce survival and proliferation of neurons through survival pathways. The phosphatidylinositol-3-kinase (PI3K) pathway and Ras- or protein kinase C (PKC)-dependent mitogen-activated protein kinase (MAPK) pathway have been extensively studied as survival pathways. Activated PI3K leads to downstream Akt phosphorylation and activation. Notably, Akt activation converges with death receptor-mediated receptor interacting protein (RIP) activation on the phosphorylation of the I κ B kinase (IKK) complex and the resulting I κ B degradation. I κ B degradation releases active nuclear factor κ B (NF- κ B) leading to transcription of genes necessary for cell survival. Similarly, activation of MAPK will lead to nuclear translocation of MAPK together with other transcription factors and co-activators and initiate the transcription of a variety of survival genes. Though not limited to those survival pathways, cytokines and growth factors such as NGF, GDNF, and BDNF play a role in protecting, repairing, and/or regenerating neurons. Neurons constantly receive survival and apoptotic signals from the extracellular environment, influencing the lifespan of each individual cell. Various cytokines such as BDNF or NGF increase during diseases and may be a compensatory mechanism to the neural injury of the CNS (Soontornniyomkij et al., 1998; Boven et al., 1999). IL-1 β from the IL-1 family or IL-6 from the type I cytokine family can activate the NF- κ B pathway, thus potentially promoting survival of neurons. Interestingly, IL-1, TNF and even TRAIL signaling pathways also converge on I κ B degradation and NF- κ B activation. IL-6 also activates the Ras-dependent MAPK pathway. Regarding IL-1 β , the activation of NF κ B and MAPK initiates transcription of a variety of genes for either survival or the inflammatory response, dependent upon cell type (Srinivasan et al., 2004).

Although chemokines act through specific GPCRs, chemokines relate to cytokines through many overlapping intracellular signaling pathways. One of the first signaling pathways identified was the inhibition of adenylyl cyclase activity to reduce the intracellular cAMP levels, modulated by the G α subunit of the Gi/o proteins (Damaj et al., 1996). It was also

FIGURE 15.1. Cytokine driven inflammatory process in multiple disease states. Multiple disease states have similar cytokine-driven inflammatory process. In HAD, HIV-1 infection of macrophage in the CNS leads to the activation of macrophage and microglia. Activated macrophage and microglia release cytokines, chemokines, and growth factors, and may have overall detrimental effects toward neurons for extended periods of time. Neuronal injury recruits additional macrophages. This injury, recruitment, and activation process forms a positive feedback loop and can aggravate various disease states. In AD and MS, either A β priming or T cell-mediated macrophage/microglia activation may utilize similar inflammatory cytokines and chemokines to cause the pathogenic effects on the CNS.

reported that most of the chemokine receptors are able to activate phospholipase C to increase the generation of diacylglycerol and inositol 1,4,5-triphosphate, with a subsequent increase in PKC activity and transient elevations of cytosolic Ca^{2+} concentrations, respectively (Kuang et al., 1996). Several chemokines (SDF-1, for example) have been reported to activate the MAPK cascade, involving ERK1/2 activation. SDF-1 also activates the downstream transcription factor Ets, a substrate

for ERK phosphorylation (Ganju et al., 1998). In most cases this activation involves effects mediated by the β subunit of a PTX-sensitive G protein and the activation of the Ca^{2+} -dependent protein kinase Pyk2. PI3-K and subsequent activation of protein kinase B is another transduction pathway activated by multiple chemokines. The JAK/STAT pathway has also been implicated in α and β chemokine receptor signaling (Mellado et al., 2001). Despite the structural similarities among chemo-

kine receptors, they can activate specific transduction pathways leading to diverse responses, an expression of the pleiotropic signal effects carried out by these proteins.

In summary, various families of cytokine, growth factor, and chemokine may greatly influence the apoptotic or survival pathways of neurons and inflammatory state in the CNS. The understanding of signaling pathways activated by cytokines, growth factors, and chemokines continues to increase. However, it is still unclear what specific pathways regulate inflammatory process in neurodegeneration and neuroimmunologic diseases.

15.4. Cytokines in Neurodegenerative and Neuroimmunologic Diseases

Many cytokines have been suggested to participate in neurodegeneration and neurotoxicity. Increases in factors such as TNF- α and IL-1 β have been observed before neuronal death (Esser et al., 1996; Matusevicius et al., 1996; Guo et al., 1998; Meda et al., 1999; Little and O'Callaghan, 2001). However, the comprehensive effect of pro-inflammatory cytokines such as IL-1 β and TNF- α is controversial. Neither of these cytokines causes neuronal death in healthy brain tissue or normal neurons (Gendelman and Folks, 1999). But it is generally believed that in disease states those proinflammatory cytokines contribute to the uncontrolled inflammation in the CNS. The effect of cytokines in each individual disease will be discussed in the following sections.

15.4.1. Cytokines in HAD

HIV-1 infection notoriously attacks the immune system in the periphery, but also can lead to a viral induced dementia. The mechanism has yet to be fully elucidated, but cytokines have been shown to play a significant role in disease progression. HIV-1 usually enters the brain shortly after initial infection, crossing the blood brain barrier through peripherally infected monocytes (Koenig et al., 1986). Brain macrophages and microglia, unlike other cellular residents in the CNS, are able to sustain a productive infection within the brain (Eilbott et al., 1989). Thus, while the rest of the body typically experiences a surge in viral load followed by a gradual reduction, the isolated CNS maintains a low, but sustained level of virus. Although neurons are not infected by HIV-1, a dementia specific to HIV has been described as HAD (Navia et al., 1986; McArthur, 1987).

HAD is the clinical consequence of neuronal damage. The pathologic correlate to HAD, HIV encephalitis (HIVE), is characterized by activated macrophage and microglia, as well as damage of neuronal dendrites and axons and apoptotic neurons. As a result of HIV-1 infection, the immune cells are recruited to the proximate site and produce an array of factors including cytokines and proteases yet are unable to clear the infection. The difficulty in eradicating HIV-1 infection prolongs the immune response leading to a chronic inflammatory

state. Chronic inflammation has both detrimental and beneficial effects. On one hand, these responses are essential in limiting viral spread; yet on the other hand, excessive inflammation is detrimental to resident cells such as neurons.

HIV-1 infection leading to neuronal injury and/or loss has been and remains the focus of much investigation. Interest in the toxic effects of cytokines during HAD increased when a study demonstrated HAD involved productive infection of macrophage and microglia (Wiley et al., 1986; Meltzer et al., 1990; Fischer-Smith et al., 2004), and macrophage and microglia become the major cytokine producers in the CNS upon infection (Table 15.1). Two distinct models have been proposed as mechanisms in HAD pathogenesis. The first is the direct neuronal injury model, in which viral proteins (gp120, tat and Vpr) directly interact with neurons causing neuronal injury through various mechanisms. The role of cytokines in this model has been controversial. Cytokines like TNF- α have a synergistic apoptotic effect with viral proteins tat (Shi et al., 1998) and gp120 (Kast, 2002). However, other cytokines inhibit the effects of viral proteins on neurons. For example, TGF- β 1 prevents gp120-induced neuronal apoptosis by restoring calcium homeostasis (Scorziello et al., 1997); BDNF and IL-10 can inhibit gp-120 mediated cerebellar granule cell death by preventing gp120 internalization and caspase-3 activation in vitro (Bachis et al., 2001; Bachis et al., 2003). The second model, referred to as the indirect neuronal injury model, proposes that neurons die as bystanders when excessive local concentrations of soluble pro-inflammatory and neurotoxic factors are released by infected MP and astrocytes (Figure 15.1). Studies have supported this notion including the observation that viral protein levels do not correlate with neuronal injury (Petito et al., 1994), while neuronal apoptosis correlates well with microglial activation (Glass et al., 1993; Adle-Biassette et al., 1995). Furthermore, studies have shown that cognitively impaired patients have elevated levels of inflammatory markers and activators in contrast to HIV patients without CNS impairment (Tyor et al., 1992; Sipsey et al., 1995).

Although proinflammatory cytokines such as TNF- α and IL-1 β are key molecules in the pathogenesis of HAD, other cytokines may play important roles as well. Elevated levels of IL-6, IL-2 and decreased levels of IL-4 have been reported in both CSF and brain sections of HAD patients (Perrella et al., 1992; Wesselingh et al., 1993; Griffin, 1997). These factors directly relate to the inflammatory state of brain. The activation of a Th1 immune response by infected macrophages results in the synthesis of cytokines such as IL-2 and IL-6 that activate macrophage and coordinate the immune response toward HIV-1 infection. IL-2 induces T-cell proliferation and potentiates the release of other cytokines. IL-3 and GM-CSF stimulate the production of new macrophages by acting on hematopoietic stem cells in bone marrow. New macrophages are recruited to the site of infection by TNF- α and other cytokines on the vascular endothelium that signal macrophages to leave the bloodstream and enter the tissue. Moreover, many inflammatory signals have been shown to increase HIV

replication. IL-2 and GM-CSF are both potent stimulators of HIV-1 replication in activated CD4 + T cells, and GM-CSF increases HIV-1 replication in macrophage cultures (Perno et al., 1990). The activity of type I cytokines during HIV-1 infection promotes the inflammatory response in an effort to eliminate virus, however in the CNS during HAD, type I cytokine mediated inflammation results in neuronal damage as well as facilitating the replication of HIV.

Type II cytokines are key to the balance of inflammation and regulation of response in HAD. IL-10 downregulates the expression of proinflammatory cytokines and up-regulates the expression of the anti-inflammatory agent IL-1Ra. Increased levels of IL-10 in the CSF have been reported in individuals with HIV-1 encephalitis (Gallo et al., 1994). In a recent study in an HAD SCID mouse model, mRNA levels of IL-10 were increased five-fold as compared to uninfected controls. This change is concurrent with down-regulation of proinflammatory cytokines (IL-1 β and IL-6) (Poluektova et al., 2004). Furthermore, pretreatment with IL-10 attenuated the neurobehavioral damage induced by HIV-1 gp120 in an in-vivo animal study (Barak et al., 2002). Increased type II immunomodulatory cytokines are possibly an active attempt to control inflammation and maintain or regain balance in CNS microenvironments.

IFNs have various effects on HAD pathogenesis. IFNs profoundly affect HIV-1 replication in various in-vitro systems. IFN- α and IFN- β are induced by HIV-1 infection and suppress HIV replication at multiple steps of the viral life cycle in macrophage (Gendelman et al., 1992; Gessani et al., 1994). IFN- γ enhances HIV-1 replication in CD4 + T cells in an autocrine manner, while in macrophage culture IFN- γ enhances HIV-1 replication when added prior to infection but inhibits replication when added post-infection. Although levels of IFN- γ have been shown to be elevated in HAD patients (Shapshak et al., 2004), its ultimate role is unclear. IFN- γ shapes the T-cell response and activates MP perhaps limiting viral spread, yet IFN- γ also synergistically enhances the effect of CD40L activation of macrophage. Interferons are known to target infected cells for cell-mediated elimination, but the ultimate role of interferons in HAD pathogenesis is still unclear (Benveniste, 1992).

Among the pro-inflammatory cytokines, TNF- α is the most studied. Levels of TNF- α mRNA are elevated in brain tissue collected from HAD patients (Wesselingh et al., 1993). Studies have shown that TNF- α levels in vulnerable brain regions correlate with neurological disease severity in HIV patients (Gelbard, 1999). During HAD, microglia, macrophages and monocytes show increased expression of TNF- α and TNF receptors (Tyor et al., 1992), an effect promoted by both IFN- γ and IL-1. HAART treated HAD patients have a marked decrease in soluble TNF- α levels in the cerebrospinal fluid; this drop in TNF- α coincides with decreased viral load and improvement in the neurological function of patients (Gendelman et al., 1998). TNF- α may promote neuronal demise through various mechanisms. Increased BBB permeability

and recruitment of activated immune cells facilitates viral invasion of the CNS. Synergy of TNF- α , viral proteins and excitotoxic glutamate activates glia to produce neurotoxins or leads to neuronal apoptosis directly (see review Saha and Pahan, 2003). Yet, the effects of TNF- α are complex; differing experimental systems and approaches have shown TNF- α to assume a neuroprotective role. TRAIL, another member of TNF family, is not normally expressed in the CNS. However, TRAIL has been reported to be expressed on the cell membrane of peripheral immune cells and can be cleaved into a soluble, secreted form (Ehrlich et al., 2003). The plasma level of TRAIL is increased to ng/ml ranges in HIV-1-infected patients, particularly those with high viral loads (Herbeuval et al., 2005). Upon HIV-1 infection of CNS, TRAIL is upregulated primarily by infiltrated macrophages that are HIV-1-infected or immune-activated (Ryan et al., 2004). Upregulated TRAIL has been shown to preferentially induce apoptosis in HIV-1-infected macrophages (Huang et al., 2006). Nonetheless, neurons express TRAIL-receptors and TRAIL may then cause neuronal apoptosis through direct interaction with TRAIL receptors on neurons or through macrophage death-mediated release of neurotoxins (see reviews Huang et al., 2005a, b). Thus TRAIL may be an important neurotoxic mediator in the pathogenesis of HAD.

Another proinflammatory cytokine, IL-1 is rapidly produced upon HIV-1 infection within the CNS. The induction of IL-1 has been shown to be associated with HAD (Zhao et al., 2001). IL-1 in this case serves as a very upstream signal for multiple proinflammatory cytokines, notably TNF- α and IL-6, initiating and amplifying inflammation in the brain, which is responsible for the global activation of macrophage and microglia (Chung and Benveniste, 1990; Aloisi et al., 1992; Lee et al., 1993). Direct injections of IL-1 into the CNS result in local inflammatory responses and neural degeneration (Wright and Merchant, 1992). IL-1 β directly activates HIV-1 replication in a monocytic cell line by transcriptional and post-transcriptional mechanisms independent of NF- κ B. IL-1 also synergistically enhances HIV-1 replication with multiple cytokines including IL-4 and IL-6 (Kedzierska et al., 2003).

TGF- β is expressed in the brain by astrocytes, MP, and oligodendrocytes, and has been shown to exert multiple effects on neurons and glial cells both in vitro and in vivo. Effects of TGF- β include cell cycle control, differentiation, extracellular matrix formation, hematopoiesis, and chemotaxis. Importantly in the CNS, TGF- β has key a role in regulating neuron survival and repair processes. TGF- β has also been shown to play a role in several varieties of CNS pathology including ischemia, excitotoxicity and neurodegenerative diseases such as multiple sclerosis. In mild HAD, the cerebral levels of TGF- β has an inverse correlation to IFN- α and HIV RNA; in the severe form of HAD, TGF- β is undetectable (Perrella et al., 2001). In specific culture conditions, TGF- β has neurotrophic effects similar to BDNF and NGF, but a change in conditions can shift the effect of TGF- β toward neurotoxicity (Prehn and Miller, 1996).

In summary, the various cytokines listed here all have certain associations with HAD. This body of evidence shades the inflammatory pattern of cytokine in HAD toward a chronic and detrimental effect that becomes manifest as the disease progresses. However, the cytokines discussed here do not constitute the complete list of players in HAD and other neuroimmune disorder diseases. Chemokines have a unique impact on the immune system; their role will be discussed at length below.

15.4.2. Cytokines in MS

MS is a chronic neurological disease with the hallmark pathological findings of perivascular inflammation and demyelination. Histological sections from MS patients show demyelinating plaques are distributed within the white matter of the CNS, but the most frequently affected sites are the optic nerves, the brainstem, the cerebellum and the spinal cord. Although the classic MS lesion is focal demyelination, axonal damage and neuronal dysfunction are also found in the pathology of MS (Trapp et al., 1999; De Stefano et al., 2001; Bjartmar et al., 2003). The selective loss of axons and myelin sheaths has been postulated to occur via a variety of different mechanisms. Traditionally, MS has been considered an autoimmune disorder consisting of myelin autoreactive T-cells that drive an inflammatory process, leading to secondary macrophage recruitment and subsequent myelin and oligodendrocyte destruction. However, recent detailed studies on a large collection of MS lesions have indicated that structural features of the plaques are extremely variable and the events involved in the immunopathogenesis of MS may be more complicated (Monica et al., 2005).

Recent studies of MS pathology show that the predominant cells in active lesions are lymphocytes, particularly T-cells and macrophages (Lucchinetti et al., 2000; Wingerchuk and Weinshenker, 2000). This pathology is similar to that found in experimental allergic/autoimmune encephalomyelitis (EAE), an animal model of MS, which can be induced in susceptible animals by active immunization with CNS tissue, myelin, myelin proteins, or by the transfer of auto-reactive T-cells. T-cells, upon being activated by antigen-presenting cells, become one of the primary effectors both in MS and EAE (Lucchinetti et al., 2000).

Generally Th1 activated CD4⁺ cells produce IL-1, IL-2, IFN- γ , and TNF- α to mediate inflammatory pathological processes in immune-mediated tissue damage seen in MS and EAE (Adorini and Sinigaglia, 1997). In contrast, Th2 cells produce IL-4, IL-6, and IL-10 to mediate antibody production and downregulation of Th1 cellular responses (Adorini and Sinigaglia, 1997). The inflammatory reaction in MS and EAE is associated with the upregulation of a variety of Th1 cytokines, including IL-2, IFN- γ , and TNF- α . However, the pathogenesis of MS lesions is more complex, compared to that of a pure Th1-mediated CNS autoimmune disease. Cells other than the classical Th1 T-cells may contribute to the inflammatory

process in autoimmune disease (Lucchinetti et al., 2000). For example, CD8 + class I restricted T-cells are also present and clonally expanded in MS lesions (Rohowsky-Kochan et al., 1989; Correale et al., 1997). Axonal destruction in MS lesions correlates better with CD8 + T-cells and macrophages rather than CD4 + T-cells (Kuhlmann et al., 2002). There is also evidence that Th2 cells can participate in pathologic autoimmune processes. Antibodies to both myelin-oligodendrocyte glycoprotein and MBP have been demonstrated in MS lesions and in the serum of MS patients (Wajgt and Gorny, 1983; Bernard and de Rosbo, 1991). Activated macrophage/microglia are a major cell source of excessive production of TNF- α , IL-1 β , and NO, thus they are suggested to participate in the pathology associated with MS (Li et al., 1993; Bitsch et al., 2000).

Many inflammatory cytokines, such as Fas ligand and TNF- α can trigger proapoptotic pathways, which are important effectors for neuronal death in EAE. Overexpression of Bcl2, an anti-apoptotic protein that blocks death receptor-initiated signaling events, protects mice primed to develop EAE (Offen et al., 2000). Further, elevated death ligand TRAIL expression level on blood MP of MS patients has been reported (Huang et al., 2000). Oligodendrocytes and neurons have recently been shown to be one of TRAIL's targets (Matysiak et al., 2002; Wosik et al., 2003; Aktas et al., 2005). Although inflammatory mechanisms seem to be an important aspect contributing to tissue injury in MS, the degree to which demyelination and axonal injury are a direct consequence of inflammation is still not clear. Nonetheless, the emphasis on the inflammatory aspect of the MS lesions continues to be a major impetus for therapeutic strategies to date.

Recent observations suggest the potential for T-cells, macrophage, and microglia to produce neurotrophic factors and other neuroprotective factors, which may indicate an important role for inflammation in the repair of MS lesions (Hohlfeld et al., 2000; Stadelmann et al., 2002; Gielen et al., 2003). FGF2 and PDGF have been demonstrated as factors regulating remyelination (Frost et al., 2003). CNTF family factors, such as CNTF, leukemia inhibitory factor, cardiotrophin-1, and oncostatin M have been reported to induce a strong promyelinating effect in a myelination model (Stankoff et al., 2002). NGF enhances neural growth and also has the ability to switch the T-cell phenotype from Th1 to Th2, which reduces CNS tissue damage (Villoslada et al., 2000). Interestingly, IL-1 β is crucial to the remyelination of the CNS and this activity is suggested to lead to induction of astrocyte and microglia-macrophage-derived IGF-1 (Mason et al., 2001). IGF-1 may, in addition, have antiapoptotic properties for oligodendrocytes (Mason et al., 2000).

Cytokines themselves may also be used for MS therapy. IFN- β has been in clinical use as an immunomodulatory drug for the treatment of MS for more than 10 years. Administration of IFN- β decreases the relapse rates and new MRI lesions in patients with relapsing/remitting MS (The IFN- β Multiple Sclerosis Study Group, 1993) or delay disease progression in patients with secondary progressive MS (Jacobs et al., 1996;

PRISMS STUDY GROUP, 1998). However, the exact mechanisms of action of IFN- β in MS are unknown. IFN- β is effective in preventing the IFN- γ -induced upregulation of MHC-II on antigen-presenting cells (Yong et al., 1998). In an earlier study, patients treated with IFN- γ exhibited an alarmingly high relapse rate during the initial month of treatment (Panitch et al., 1987). IFN- β can also downregulate the expression of costimulatory molecules and inhibit the activation and proliferation of T cells. Additionally, IFN- β is involved in the alteration of cytokine levels, decreasing the level of Th1 cytokine including IFN- γ , IL-12 and TNF- α (Yong et al., 1998). IFN- β treatment of astrocytes has been reported to stimulate production of NGF in-vitro (Boutros et al., 1997) and may thus promote remyelination in the CNS.

In summary, cytokines and growth factors are very important mediators in the pathogenesis of MS as well as exhibiting therapeutic potential. More effort should be brought to explore the complex interactions among immune cells, cytokines, growth factors and CNS resident cells.

15.4.3. Cytokines in AD

AD is the most common chronic neurodegenerative disorder characterized by the presence of neuritic plaques, neurofibrillary tangles, neurophil threads, and plaque deposits comprised of highly insoluble β -amyloid peptides (A β), cellular debris, and inflammatory proteins in the cerebral cortex and hippocampus (Selkoe, 2001; Ringheim and Conant, 2004). Neurons of the hippocampus and cerebral cortex are selectively lost. A number of factors have been thought to contribute redundantly to pathogenesis of AD, including unbalanced calcium homeostasis, cell-cycle protein dysregulation, excitatory amino acids, as well as DNA damage. Deposition of A β in the brain parenchyma appears to be the crucial factor for the onset of AD, although mechanisms underlying A β effects are far from understood. The precursor of A β , amyloid protein precursor (APP), is an acute-phase agent upregulated in neurons, astrocytes, and microglia in response to inflammation, stress, and a multitude of associated cellular stresses. A β at high concentrations (generally $>10\mu\text{M}$) has been found to act as a potent neurotoxic agent to both neuronal and non-neuronal cells. Interestingly, A β induces neurotoxicity through the activation of microglia (Figure 15.1). *In-vitro* studies indicate concentrations of A β as low as $1\text{--}2\mu\text{M}$ can induce neuron cell death but only in the presence of microglia (Qin et al., 2002). A β primes microglia and has been shown to directly induce an inflammatory response when injected into the rat brain.

Inflammation has been suggested to contribute to the A β deposition and neuropathology associated with AD. For example, many clinical studies have indicated that anti-inflammatory drugs have a protective effect upon the development of AD (Stewart et al., 1997; Broe et al., 2000). AD is associated with the increase of pro-inflammatory cytokines including IL-6, TNF- α , M-CSF, IL-1 β , TGF- β , TRAIL,

and PDGF (Griffin et al., 1989, 1995; van der Wal et al., 1993; Tarkowski et al., 1999; Akiyama et al., 2000; Uberti et al., 2004). These cytokines are produced by activated glia and some (IL-1 β and TNF- α) are capable of perpetuating glial activation, leading to a cycle of overproduction of these potentially neurotoxic molecules, others (TRAIL, for example) have been suggested to induce apoptosis in CNS cells directly. It should be noted, however, that these same cytokines at low concentrations may be neuroprotective. Moreover, a complex relationship seems to exist between A β deposition and the A β -induced inflammatory response. Because A β accumulation appears to trigger inflammation, factors that either promote or inhibit A β aggregation would be expected to similarly affect inflammation. Microglia isolated post-mortem from AD patients have been shown to either constitutively express cytokines, including IL-1 β , IL-6, and TNF- α , or produce these cytokines in response to A β (Lue et al., 2001). Likewise, A β and other amyloid-associated proteins are capable of stimulating the production of these same cytokines by rodent glia (Lindberg et al., 2005).

IL-1 regulates the synthesis of the APP from which the pathologic and diagnostic amyloid plaques of AD originate (Goldgaber et al., 1989). The functions of IL-1 suggest that this cytokine plays a key role in the pathogenesis of AD. Brain tissue levels of IL-1 are markedly elevated in AD, and the numbers of IL-1-immunoreactive microglia are increased in tissue sections of Alzheimer brain, mirroring the distribution of microglia within cerebral cortical layers in brains of normal controls (Sheng et al., 1998). This suggests distribution of microglia within the brain in part determines the distribution of A β plaques in AD.

In summary, cytokines and growth factors discussed in this section are implicated in the pathophysiological processes of AD of which activated microglia and macrophage perpetuate the inflammatory response that ultimately causes neuronal injury. However, it should be noted that inflammation orchestrated by cytokines, chemokines, and growth factors may only play minor roles, as some researchers regard AD as a neurodegenerative disease rather than neuroinflammatory disease.

15.5. Chemokines in the CNS

While produced most often by immune cells, chemokines are also expressed by cells within the brain including endothelial cells, neurons, astrocytes, microglia and oligodendrocytes where they regulate the migration, recruitment, accumulation, and activation of leukocytes in the brain (Wu et al., 2000). For a summary of chemokines in the CNS, see Table 15.2. Some chemokines such as stromal derived factor-1 α (SDF-1 α , CXCL12) and fractalkine (FKN, CX3CL1) are constitutively produced in the brain and likely play an important role in central nervous system (CNS) homeostasis and development. Others, such as macrophage inflammatory protein one alpha and one beta (MIP-1 α , CCL3 and MIP-1 β , CCL4), monocyte chemotactic

TABLE 15.2. Chemokine ligands and receptor expression in CNS inflammation.

Cell type	Ligands chemokine (systematic name)	Receptors	Reference
Monocytes/Macrophage	MCP-1 (CCL2), MIP-1 α / β (CCL3/CCL4)	CCR2	(Bernasconi et al., 1996; Cinque et al., 1998; Kelder et al., 1998; Sorensen et al., 1999; Collman et al., 2000; Gabuzda et al., 2002; Mizuno et al., 2003)
	RANTES (CCL5)	CCR3, CCR5	
	IL-8 (CXCL8)	CCR3, CCR5	
Microglia	IP-10 (CXCL10)	CXCR3	(Bernasconi et al., 1996; Ishizuka et al., 1997; Cinque et al., 1998; Kelder et al., 1998)
	MIP-1 α / β (CCL3/CCL4)	CXCR4, CCR4	
		CCR3, CCR5	
Astrocytes	RANTES (CCL5)	CCR3, CCR5	(Conant et al., 1998; Simpson et al., 1998; Zheng et al., 1999b, 2000b)
	MCP-1,3 (CCL2,CCL7)	CCR2	
	IL-8 (CXCL8)		
	IP-10 (CXCL10)	CXCR3	
	MCP-1 (CCL2)	CCR4, CXCR4, CX3CR1	
		CCR2	
Neurons	MIP-1 α / β (CCL3/CCL4)	CCR3, CCR5	(Xia et al., 1997; Coughlan et al., 2000; Zheng et al., 2000b; Xia and Hyman, 2002)
	RANTES (CCL5)	CCR3, CCR5	
	SDF-1 α (CXCL12)	CXCR4	
	IL-8 (CXCL8)		
	IP-10 (CXCL10), FKN (CX3CL1)		
		CCR4	
Endothelium	FKN (CX3CL1)	CX3CR1	(Gabuzda et al., 2002)
	MCP-1 (CCL2)	CCR2	
		CCR5, CXCR4	
	GRO- α (CXCL2)	CXCR2	
		CXCR3	
	IL-8 (CXCL8)	CXCR4, CCR5	(Gabuzda et al., 2002)
	FKN (CX3CL1)		
	IP-10 (CXCL10)

	MIG (CXCL9)		
	MCP-1,3,4 (CCL2, 7, 13)		

protein-1 (MCP-1, CCL2), and the regulated upon activation normal T-cell expressed and secreted (RANTES, CCL5), are induced by inflammatory stimuli. These chemokines are likely involved in the pathogenesis of a variety of neurodegenerative diseases, where inflammation plays a role in pathogenesis, such as MS, AD, and HAD.

15.6. Chemokines and their Receptors in Neurodegenerative and Neuroimmunologic Diseases

The inflammatory response manifest in the brain during HIV-1 infection of the nervous system leads to the development of a chemo-attractant gradient resulting in the formation of multinucleated giant cells in HIVE (Williams et al., 2002). This enables inflammatory monocyte-derived macrophages

(MDM) to enter the brain, become infected and expand the sources of neurotoxic secretory factors that lead to the pathological and clinical aspects of disease (Gendelman et al., 1997). Moreover, chemokine receptors are critical for infection in perivascular macrophages and microglia. Studies have shown chemokines and their receptors play a more direct role in the neuropathogenesis of HIV-1 infection. It is now clear that neurons, glia and neural stem cells express chemokine receptors and the interactions of HIV-1 gp120 with neuronal chemokine receptors leads to apoptosis of neurons (Kaul et al., 2001; Cotter et al., 2002; Ryan et al., 2002; Tran and Miller, 2003; Peng et al., 2004). These effects may be manipulated by chemokines that act on the same receptors. The presence of chemokine receptors on neural cells also supports the notion that chemokines modulate neuronal physiological functions. Thus, chemokine receptors might have a crucial role in the balance between neuronal protection and injury.

15.6.1. Chemokines and Their Receptors in HAD

15.6.1.1. *HIV-1, Chemokines and HIV-1*

Co-receptors

As previously discussed, chemokines are important players in the development and maintenance of an immune response to foreign insult. In some circumstances however, chemokines play a more central role in the pathogenesis of the disease process. Studies have shown multiple viruses including herpesvirus, poxvirus, retrovirus, and lentivirus take advantage of the chemokine system, posing as analogs, to presumably gain a survival advantage by avoiding or altering immune detection and elimination (Murphy, 2001). Another manipulation of chemokine immune defense first described in 1996, is HIV's use of a chemokine co-receptor in human infection (Feng et al., 1996). Initially, HIV was assumed to rely solely on the CD4 surface protein found on T-cells and macrophages for entry into host cells (CD4 as an HIV receptor is reviewed in Sattentau and Weiss, 1988). However, CD4 alone did not accurately predict the cell interactions of HIV. This eventually led to the breakthrough that chemokine GPCRs mediate viral membrane fusion with human host cells. Each HIV strain has different specificities and interactions with various chemokine receptors, but the two primary coreceptors are CCR5 and CXCR4. Macrophage or M-tropic viral strains utilize CCR5 for infection; T-cell or T tropic viral strains rely upon CXCR4. There is another viral subset, dual tropic or R5X4 strain that employs both coreceptors. Further, additional receptors have been shown to have more limited viral interactions including CCR2, CCR3, CCR8, CX3CR1 and others, but the pathophysiological relevance has yet to be determined (Gabuzda and Wang, 2000).

The co-receptor requirement is a result of receptor ligand interactions between the chemokine GPCRs and the HIV coat protein gp120. Virus-cell interactions characteristically begin with gp120 binding CD4, inducing a conformational change in gp120. This change alters the affinity of gp120 for a coreceptor, either CCR5 or CXCR4 resulting in a trimolecular interaction between gp120, CD4 and the coreceptor (Berson and Doms, 1998; Dimitrov et al., 1998; Berger et al., 1999). The multi-molecular interaction then permits fusion of HIV viral membrane to the host cell, allowing entry and consequent integration into the host DNA.

Within the past several years the links between chemokines, chemokine receptors, and HIV pathogenesis have been shown to be clear and significant (Cocchi et al., 1995; Deng et al., 1996; Dragic et al., 1996; Feng et al., 1996; Michael, 2002; Rizzardi et al., 2002). Chemokine receptors play a critical role, particularly in the early stages of HIV cell entry both in protective and liable capacities. Chemokine receptors CCR5 and CXCR4 are the major co-receptors for viral entry into CD4+ cells (Cocchi et al., 1995; Deng et al., 1996; Dragic et al., 1996; Feng et al., 1996), whereas the presence of chemokines can sometimes help prevent infection. These observations have elicited intense interest in chemokine biology.

Neurons express both chemokines and chemokine receptors, and although not infected by HIV, neurons do express the coreceptors CXCR4 (Zhang et al., 1998) and CCR5 (Rottman et al., 1997). Similar to cells infected by HIV, the neuron coreceptors have affinity for HIV envelope protein gp120, regardless of CD4. Many groups have since shown neuronal toxicity mediated by viral proteins, particularly gp120 (Hesselgesser et al., 1998; Kaul and Lipton, 1999; Ohagen et al., 1999; Zheng et al., 1999b; Chen et al., 2002; Garden et al., 2004). Upon interaction with coreceptors, gp120 induces signaling cascades that may play a role in promoting apoptosis. Blocking of these cascades can block neuronal death in some cases. Interestingly, different viral strains induce varying levels of neuronal toxicity (Gabuzda and Wang, 1999; Zheng et al., 1999a).

15.6.1.2. *Neuroprotective and Neurotoxic Effects of Chemokines and Their Receptors in HAD*

In contrast to HIV-1 coreceptors, some chemokine ligands have the ability to reduce or ablate neuron toxicity. High levels of chemokines RANTES, MIP-1 α , and others have been shown to reduce neuron death (Meucci et al., 1998; Kaul and Lipton, 1999), while SDF-1, at higher concentrations may actually promote neuronal death (Hesselgesser et al., 1998; Kaul and Lipton, 1999; Zheng et al., 1999b). The mechanism is not yet completely understood, but may rely upon simple competitive inhibition, receptor expression changes on the cell surface, or other unknown mechanisms.

Fractalkine (CX3CL1): FKN levels are higher in the CSF of cognitively impaired HIV patients than in infected subjects without cognitive impairment. Moreover, FKN can affect the chemotaxis of primary monocytes across an artificial blood brain barrier and is neuroprotective to cultured neurons (Meucci et al., 2000; Tong et al., 2000). Thus, this neuronal chemokine may serve as a damage signal to recruit macrophages and microglia to the site of injury (Jung et al., 2000; Tong et al., 2000; Zheng et al., 2000a; Zujovic et al., 2000). Subsequent chemokine-MP interactions can initiate inflammatory responses through the production of chemokines/cytokines or protective responses through the production of neurotrophins (Xiao and Link, 1998; Kaul et al., 2001; Cotter et al., 2002).

MCP-1 (CCL2): Despite some association of chemokines and neuroprotection, there are also detrimental effects of chemokine function during HAD pathogenesis. Shown to be expressed in the brains of HAD patients (Conant et al., 1998), MCP-1 (CCL2) is a potent chemoattractant for monocytes and may help fuel the positive feedback loop of inflammation in the HAD brain. MCP-1 recruits monocytic phagocytes to sites of inflammation as was evidenced by a study using a mouse system with elevated levels of MCP-1 resulting in increased phagocytic cells at lesion sites (Fuentes et al., 1995). A high level of MCP-1 in CSF versus plasma was shown to be predictive of dementia development in monkeys (Zink et al., 2001). While clearly possessing chemotactic properties, the ability of MCP-1 to recruit phagocytes through the BBB was further elucidated with a study showing changes in BBB permeability

in the presence of MCP-1 (Song and Pachter, 2004). Increased levels of MCP-1 were shown to result in initial protection from infection, however, upon successful HIV-1 infection, increased MCP-1 was shown to lead to increased susceptibility to the development of HAD (Gonzalez et al., 2002).

Interferon-inducible protein 10 (IP10, CXCL10): IP-10 is a CXC chemokine. As indicated by its name, IP-10 is highly induced by interferon as well as other factors, yet is also produced constitutively throughout the body. IP-10 targets multiple subtypes of activated T-cells and macrophages for migration. IP-10 has been found in very high levels in CSF as well as shown to recruit cells into the CNS in the setting of HAD. While clearly a player in recruitment and inflammation, IP-10's role has also been shown to include cytotoxic effects toward neurons (van Marle et al., 2004) and may stimulate HIV-1 replication in macrophages (Lane et al., 2003).

IL-8 (CXCL8): An endogenous ligand for CXCR2, IL-8 is secreted in high levels by HIV-1 infected lymphocytes and macrophages. Although expressed constitutively, immune activation potentiates IL-8 production from infected or uninfected macrophages by agents such as LPS or CD40L (Zheng et al., 2000b). IL-8 levels are increased in the CSF of HAD patients, more so than those lacking cognitive symptoms, supporting the role IL-8 in HAD (Zheng et al., 2001).

SDF-1 (CXCL12): Chemokines have also been shown to have a neuromodulatory capacity, in some cases decreasing excitation and avoiding toxicity. A complicated example is the effect of SDF-1 on glutamate toxicity and uptake, specifically as regulated through astrocytes. SDF-1 is a member of the CXC chemokine subfamily and is the only known physiological ligand for CXCR4 (Rossi and Zlotnik, 2000). CXCR4 is upregulated in HIV and SIV encephalitis, experimental allergic encephalitis (EAE), and brain tumors (Jiang et al., 1998; Sanders et al., 1998; Vallat et al., 1998; Westmoreland et al., 1998). SDF-1 is a potent chemoattractant for resting lymphocytes, monocytes, and CD34-positive hematopoietic progenitor cells (Kim and Broxmeyer, 1999). SDF-1 transcripts are predominantly expressed by oligodendrocytes, astrocytes and neurons in the cortex, hippocampus, and cerebellum (Gleichmann et al., 2000; Stumm et al., 2003). SDF-1 has been shown to be upregulated in the brain of patients with HIV and in astrocytes by HIV-1-infected and/or immune-activated macrophages *in-vivo* (Langford et al., 2002; Rostasy et al., 2003; Peng et al., 2006). Studies conducted in different settings have shown SDF-1 to promote neuronal survival, reducing glutamate toxicity (Meucci et al., 1998), while other studies have shown SDF-1 to increase neuronal death by interacting with CXCR4 and increasing the release of glutamate and TNF- α from glial cells (Meucci et al., 1998; Kaul and Lipton, 1999; Zheng et al., 1999b; Bezzi et al., 2001; Kaul et al., 2007). This may be due to experimental variation or a concentration dependent effect of SDF-1 and glutamate regulation. Recently, it was suggested that SDF-1 could be cleaved to SDF-1 (5–67) and mediate direct neurotoxicity through CXCR3 (Zhang et al., 2003; Vergote et al., 2006).

15.6.1.3. *Therapeutic Avenues Directed Toward Chemokines and Their Receptors*

Because HIV requires coreceptors for the induction of productive viral infection and naturally occurring alleles have been shown to effectively limit HIV entry (reviewed in Tang and Kaslow, 2003), potential therapies may rely upon exploitation of CXCR4 and CCR5. However, the ability of HIV to mutate presents a great hurdle in the development of effective therapeutic receptor antagonists. Another layer of complexity is the potential side effects of blocking one or multiple chemokine receptors that have homeostatic and inflammatory roles. Despite the inherent difficulties, multiple approaches have been studied and some are now being tested in clinical trials. Small molecule inhibitors, monoclonal antibodies, and modified chemokine ligands are all related but distinct approaches to limiting HIV entry currently being developed and tested (reviewed in Shaheen and Collman, 2004). Another approach to block initial HIV infection may be to deliver siRNAs targeting the receptors for knockdown (Zhou et al., 2004).

Some chemokine ligands inherently disrupt viral pathogenesis or provide protection against cell death during the disease process. Ligands of HIV coreceptors, such as SDF-1 and RANTES, have been shown to block infection of cells in different systems (Bleul et al., 1996; Lederman et al., 2004). Similarly, ligands to coreceptors have been shown to block HIV envelope protein induced toxicity to neurons (Alkhatib et al., 1996; Meucci and Miller, 1996). The mechanism may be simple blocking or internalization of receptors, or may rely upon the signaling downstream of chemokine interaction.

15.6.2. *Chemokines and Their Receptors in MS*

Similar to cytokines, the chemokine expression pattern is also a Th1-mediated response in MS. Pro-inflammatory cytokines activate resident macrophages and microglia within the CNS (Figure 15.1). Recruitment and attraction of these cells occurs via integrins and chemokines and is believed to contribute to tissue injury and demyelination. Selective expression of individual chemokines may influence the cellular composition of inflammatory lesions because chemokine receptors are associated with either Th1 or Th2 responses. Th1 proinflammatory cells may express CCR5 (receptor for chemokines RANTES, MIP-1 α and MIP-1 β) and CXCR3 (receptor for IP-10 and MIG), whereas Th2 inflammatory cells may shift toward the display of CCR3 (receptor for MCP-3, MCP-4, and RANTES) and CCR8.

In MS autopsy brain sections, CCR5 and CXCR3 are over-expressed in peripheral and lesion associated T-lymphocytes (Simpson et al., 1998; Balashov et al., 1999). The ligands for CCR5 and CXCR3, RANTES and IP-10, also increase in the CSF (Lucchinetti et al., 2003). For the cell source of chemokines, IP-10 was associated with astrocytes and perivascular astrocytic processes within MS lesions (Simpson et al., 1998; Balashov et al., 1999; Sorensen et al., 1999). These results suggested that the interaction between IP-10 and CXCR3 might be the mechanism that traffics T-cells into MS lesions.

Similarly, elevated CCR5 in activated macrophages was found in MS lesions, indicating RANTES might mediate the recruitment and activation of monocytes and macrophages in MS (Sorensen et al., 1999). Further, MCP-1, MCP-2, MCP3, MIP-1 α , and MIP-1 β immunoreactive astrocytes within MS lesions have been described (McManus et al., 1998; Simpson et al., 1998; van der Voorn et al., 1999; Boven et al., 2000). These results were supported by the study in the EAE model, particularly MCP-1 (Ransohoff et al., 1993; Berman et al., 1996), IP-10 (Ransohoff et al., 1993), RANTES (Godiska et al., 1995).

Taken together, these results indicate extensive chemotactic interactions between the glia cells in MS lesion and the infiltrating cells. Whether these interactions ultimately promote destructive inflammation or recruitment of viral and protective regulatory cells that enhance tissue repair is still not clear. This is a crucial question to answer before potential pharmacological intervention based on chemokines and their receptors could be reinforced for the treatment of the MS.

15.6.3. Chemokines and Their Receptors in AD

Immunohistochemical analysis of tissue from human brains with AD have revealed that in AD, there is increased expression of MIP-1 β and IP-10 by activated astrocytes, and of the chemokine receptors CCR3 and CCR5 on activated microglia, adjacent to A β deposits in AD (Xia et al., 1998, 2000). Dystrophic neuritis has been shown to express the IL-8 receptor CXCR2 within the A β plaques of AD (Xia et al., 1997). A β is capable of modulating the inflammatory processes involved in AD through chemokine production. MCP-1 is found in activated microglia and within neuritic A β plaques, but not in early plaque forms (Ishizuka et al., 1997). A β promotes production of MCP-1, MIP-1 α , MIP-1 β , or IL-8 by monocytes and microglia (Fiala et al., 1998; Meda et al., 1999); A β also promotes expression of MCP-1 and RANTES by astrocytes (Johnstone et al., 1999). These observations collectively suggest that chemokines may play a role in the pathogenesis of AD (Xia and Hyman, 1999). It is likely that the production of chemokines by the surrounding cells plays a role in the recruitment and accumulation of astrocytes and microglia in senile plaques (Cartier et al., 2005).

Although the exact role of chemokines in AD is still not yet well defined, neuroprotective effects of chemokines have been noted. Fractalkine/CX3CL1 is suggested to have a protective role in AD. It has been reported that Fractalkine/CX3CL1 inhibits the production of IL-6, TNF- α and NO with A β -primed microglia, thereby improving the neuronal survival rate (Zujovic et al., 2000; Mizuno et al., 2003). GRO- α (CXCL2), the ligand for CXCR2 has been suggested to trigger ERK1/2 and PI-3K pathway in a way similar to BDNF, indicating GRO- α , or perhaps other CXCR2 ligands, could have a neurotrophic effect (Xia and Hyman, 2002). Neuroprotective effects of other chemokines, such as RANTES, SDF-1 α , IP-10, and MIP have also been documented (Meucci et al., 1998).

With the current understanding of chemokines and their related regulations, it is unlikely that pharmaceutical intervention

will soon be used to treat AD. New therapeutic modalities targeting chemokines and their receptors may become available as a more detailed understanding of chemokines, their receptors, and potential agents in inflammatory changes is garnered.

Summary

The role of cytokines, growth factors, and chemokines in neuroimmune dysregulation is complex, due to the overlapping, synergizing, and antagonizing effects of various factors. Classifying any individual factor or family of factors as beneficial or detrimental oversimplifies the interactions between various cell types and the signaling cascades initiated by them. Instead, cytokines need to be considered as a balanced network, where subtle modifications can shift cells toward different outcomes such as death, proliferation, migration, and induction of inflammation or inhibition of immune responses. Prolonged inflammation has a profound impact on the cytokine network and the cells they target, consequently altering the outcome of cell populations. The CNS is a unique environment that is exquisitely sensitive to cytokines, growth factors, and chemokines; the dysregulation that is rampant during neurodegenerative diseases permanently transforms brain function. The profile of cytokines, growth factors, and chemokines presented in the brain influences the function and ultimately the fate of neurons. Understanding the effects of cytokines, growth factors, and chemokines and how the expression or activity of those factors can be manipulated may provide the key to diagnosing or treating neuroimmunological disease.

Review Questions/Problems

1. What is a cytokine?
2. How does IL-1 β contribute to the development of HIV-1 associated dementia, Alzheimer's disease, and multiple sclerosis?
3. List five members of TNF family of cytokine and their effects in CNS inflammation.
4. List three major families of neurotrophic factors.
5. How do different stimuli lead to CNS inflammation in the pathogenesis of HIV-1 associated dementia, Alzheimer's disease, and multiple sclerosis?
6. Briefly discuss the approach to classify chemokines and provide an example for each type.
7. Describe the two distinct means in which chemokine receptors participate in the pathogenesis of HAD.
8. Which chemokine receptors have been identified as coreceptors for HIV?

9. **Compare two distinct models on how HIV-1 leads to neuronal injury.**
10. **Mitochondria play a pivotal role in mediating signaling events leading to apoptosis. Briefly describe the mitochondrial apoptosis pathway in a sequential order.**
11. **Which of the following statements about chemokines is correct?**
 - a. Chemokines and chemokine receptors play a significant role in pathogenesis of inflammatory disorders, such as HIV-1 associated dementia.
 - b. Stromal derived factor-1 α (SDF-1 α , CXCL12) and fractalkine (FKN, CX3CL1) are constitutively produced in the brain.
 - c. Macrophage inhibitory proteins one alpha and one beta (MIP-1 α , CCL3 and MIP-1 β , CCL4), and monocyte chemotactic protein-1 (MCP-1, CCL2) could be induced by inflammatory stimuli in the CNS.
 - d. All of the above are correct.
12. **Propose a potential therapeutic approach using a cytokine or chemokine in HIV-1 associated dementia.**
13. **Which of the following statements are FALSE in regards to inflammatory cytokines and chemokines in relationship to neurodegenerative diseases?**
 - a. Microglia, brain macrophage and astrocytes are major sources of inflammatory mediators for disease.
 - b. Pro-inflammatory cytokines mediate neurodegeneration through the upregulation of neurotrophic factors including NGF, BDNF, and NT-3.
 - c. Chemokines such as MCP-1 Promote inflammation through recruitment of monocyte-derived macrophages that propagate tissue damage.
 - d. Activated microglia may contribute to tissue damage.
14. **The following belongs to TNF family members EXCEPT?**
 - a. CD40L
 - b. TRAIL
 - c. FasL
 - d. TGF
15. **The following cytokines serve as pro-inflammatory factors EXCEPT?**
 - a. IL-10
 - b. IL-1
 - c. IFN-
 - d. IL-6
16. **Which of the following statements about type I and type II cytokines are incorreced?**
 - a. Type I and type II cytokine families are classified based upon the structural homology of their receptors.
 - b. Type I and type II cytokine families are comprised of both Th1 and Th2 cytokines.
 - c. Interferons are type II cytokines that promote viral growth while serving as anti-inflammatory and immunomodulatory factors.
 - d. Members of the type I cytokine family share a characteristic motif consisting of an extracellular region containing four helices.
17. **Which anti-HIV therapeutics specifically target the infecting agent?**
 - a. Co-receptors: CCR5 and CXCR4
 - b. Viral receptor: CD4
 - c. Viral enzymes required for replication
 - d. Adenylate cyclase
18. **The chemokine co-receptors for HIV-infection infection are?**
 - a. CXCR7 and CCR1
 - b. CCR1 and CCR5
 - c. CXCR4 and CCR1
19. **ELR+ chemokines target which cell type?**
 - a. Monocytes and lymphocytes
 - b. Neutrophils
 - c. Progenitor cells
 - b. Monocytes
20. **Chemokines are defined by the organization of their N-terminal cysteine residues. Which of the following is not representative of a chemokine classification?**
 - a. CC
 - b. CXC
 - c. CXXC
 - d. C
21. **Which of the following is the most potent chemoattractant for monocytes and macrophages?**
 - a. CXCL12
 - b. CXXXCL3
 - c. CCL2
 - d. CXCL8

Acknowledgments. This work was supported in part by research grants by the National Institutes of Health: R01 NS 41858, P20 RR15635 and P01 NS043985 (JZ). We kindly acknowledge Dr. Howard E. Gendelman for valuable suggestion and critics of this work. Hui Peng, Robin Cotter, Lisa Ryan, Shelley Herek, David Erichsen, Alicia Lopez, Li Wu, Clancy McNally, Min Cui, Jianxing Zhao, Angelique Walstrom, and Anastasia Persidsky provided technical support for this work. Julie Ditter, Robin Taylor, Myhanh Che, Nell Ingraham and Emilie Scoggins provided outstanding administrative support.

CNS Cell Signaling

Ramendra N. Saha, Keshore R. Bidasee, and Kalipada Pahan

Keywords Signal transduction; CNS homeostasis; Glial activation; JAK-STAT pathway; MAP kinase pathways; Myelination; Neurodegeneration; Neuroinflammation; Neuronal apoptosis; Neuroregeneration

16.1. Introduction

What mysterious forces precede the appearance of these processes... promote their growth and ramification...and finally establish those protoplasmic kisses...which seem to constitute the final ecstasy of an epic love story.

~Santiago Ramón y Cajal [1852–1934]

The science of neurobiology is now almost a century older than times when Spanish neuroanatomist and Nobel laureate Santiago Ramón y Cajal had wondered as above. Yet, these ‘mysterious forces’ have only been partially illuminated today and the posed question still remains worth pondering upon in contemporary times. What Cajal identified as ‘forces’ are basically key cellular signals that are transduced preceding growth and ramification. A precipitate of our knowledge today tells us that these ‘forces’ are mostly generated within and amongst members of the central nervous system (CNS). The present chapter is aimed at appreciating cellular signals and their transduction pathways which underlie the functional output of CNS during normal times, diseased conditions, and regeneration.

16.2. An Introductory Orientation

Signal transduction forms the basis of cellular perception to an external signal. Generally, it refers to defined and regulated cascade of cellular events that identifies a certain signal at cell surface or in intracellular compartments (reception desk) followed by engagement of second messenger pathway(s) that finally enable the cell to respond to the signal.

16.2.1. General Mechanism of Cellular Signal Transduction

Ideally, there are four stages in any signal transduction pathway. The first stage involves binding of receptors by the ligand. These receptors could be intracellular (e.g. nuclear hormone receptors), or may be exhibited on the plasma membrane. The second stage involves activation of receptors in response to ligand binding. Once activated, the receptor recruits several modulators (e.g. G-proteins) as the third step in the cascade. Finally, in the fourth step, second messengers (e.g. cAMP, ceramide) are activated which convey the signal downstream to effector molecules (e.g. transcription factors, which translocated to the nucleus and induce activation of specific genes). Although most signal transduction pathways are structured around four-stage process, yet variations are also observed.

For a signal to be able to induce an appropriate response to the inducer, it must be specific, fast, and must be amplified along the way of transduction. Indeed, amplification is achieved when one receptor recruits several modulators, which in turn activate several second messengers (Figure 16.1).

16.2.2. Signaling in CNS: A Complex Web of Signaling in Various Cell Types

Previous chapters of this book should have by now impressed the reader with the complexity of cellular types and function in CNS. The main cell types bathing in cerebro-spinal fluid are neurons, astrocytes, microglia, oligodendroglia, and Schwann cells. Additionally, there are endothelial cells lining the blood-brain barrier (BBB). These cells, despite having distinguished functions of their own, are remarkably interconnected and demonstrate considerable amount of inter-cellular signaling between similar or dissimilar cells. Such crosstalk between different cell types forms the basis of several physiological outcomes like memory formation and axonal regeneration. Despite sharing several common signaling pathways, yet, sometimes same ligands induce strikingly opposite outcomes

in different CNS cells. For example, few inducers of inflammatory response in glia cause degeneration of neurons. This suggests that there are cell-type-specific modulations of certain signaling pathways.

16.3. Signals Maintaining Normal CNS Health and Function

16.3.1. Major Signaling Pathways Maintaining CNS Homeostasis

Regulation and/or maintenance of axonal growth, dendritic pruning, synaptogenesis and synaptic refinement, and neuronal survival/death are essential for the proper functioning of the nervous system. These functions are carried out following the interaction of neurotrophins with their plasma membrane receptors, Trk receptor tyrosine kinases (Trks) and p75 neurotrophin receptor (p75^{NTR}) and increase in cytoplasmic Ca²⁺. In the mammalian brain four neurotrophins have been identified: nerve growth factor (NGF); brain-derived neurotrophic factor (BDNF); neurotrophin 3 (NTF3) and neurotrophin 4 (NTF4, also referred to as NTF4/5) (Zweifel et al., 2005; Lu et al., 2005). Trk family of receptor tyrosine kinases comprises of three different receptors, Trk A, Trk B and Trk C. p75^{NTR} is a member of the tumor necrosis receptor super family (Huang and Reichardt, 2003). In general, activation of Trk receptors stimulates neuronal survival, differentiation, neurite outgrowth, synaptic plasticity, and function. p75^{NTR} acts as a facilitator of Trk-mediated neuronal survival as well as an inhibitor of cell growth and promoter of apoptosis (Nykjaer et al., 2005).

Neurotrophins are synthesized as proneurotrophin precursors of ~27–35 kDa. These precursors of neurotrophins are cleaved either within the cell by the serine protease Furin (trans-Golgi network) and pro-convertase or in the extracellular space by the plasmin and matrix metalloproteinases (MMP3 and MMP7), affording mature neurotrophins of about 13 kDa. While mature NGF preferentially binds to and activates Trk A ($K_D \sim 1$ –10 nM), BDNF and NTF4 (NTF4/5) exhibit high affinity for Trk B. On the other hand, NTF3 binds to and activate Trk C. Mature neurotrophins have slightly lower and similar affinities for p75^{NTR}, while proneurotrophins exhibit high affinity for p75^{NTR} (Barker, 2004).

16.3.1.1. Trk Receptor Signaling

The extracellular domain of Trk receptors is made up of three leucine-rich 24 residue motifs flanked on either side by a cysteine cluster (C1 is on the outer side and C2 is in the inner side), followed by two immunoglobulin (Ig)-like domains and a single transmembrane domain. The cytoplasmic domain of Trk receptors contains several tyrosine motifs (Huang and Reichardt, 2003). The major ligand binding site on Trk receptors is located in the region proximal to the Ig-

C2 domain. Binding of neurotrophins to Trk receptors triggers receptor dimerization, autophosphorylation of tyrosine residues and activation of several signaling pathways. There are ten conserved tyrosine residues in each Trk receptors. Phosphorylation of Y670, Y672, and Y675 potentiate tyrosine kinase activity by pairing these negatively charged residues with basic residues in their vicinity. Phosphorylation of additional residues creates docking sites for adaptor proteins including Ras-Raf-MEK-Erk-CREB, PI3-kinase-Akt, PLC γ -Ca²⁺, NF- κ B and atypical protein kinase pathways. In Trk A receptor, phosphotyrosine 490 creates a docking site for Shc, fibroblast growth factor receptor substrate 2 (FRS2) which then activates Ras and PI3 kinase. However, phosphorylation of 785 residue recruits PLC γ -1. Activation of these pathways leads to local control of axonal growth, neuronal survival and metabolism.

Neurotrophin-Trk receptor complexes are internalized and retrogradely transported from distal axons to the neuronal cell body where they signal to the soma to mediate target-dependent survival, growth and gene expression. The neurotrophin-Trk receptor complex is internalized by four mechanistically diverse and highly regulated pathways: macropinocytosis; clathrin-mediated endocytosis; caveolae-mediated endocytosis and Pincher-mediated endocytosis. The kinase activity of Trk is probably required for receptor internalization.

16.3.1.2. p75^{NTR} Receptor Signaling

p75^{NTR} is the second class of neurotrophin receptor that is integral for maintaining CNS health and function (Barker, 2004; Lee et al., 2001; Meldolesi et al., 2000). This receptor binds soluble dimeric ligands and often requires (or act as) a co-receptor to facilitate neuronal survival, neuronal death and growth inhibition. Structurally, p75^{NTR} is less complex than Trk receptors. The extracellular domain comprises of four tandemly arranged cysteine-rich motifs that contain the neurotrophin binding site. This is followed by a single transmembrane domain and a cytoplasmic tail. Unlike Trk receptors, the cytoplasmic tail of p75^{NTR} receptor does not possess kinase activity. However, the cytoplasmic tail of p75^{NTR} possess three intracellular domains that serve as docking sites for adaptor proteins. They include a domain with homology to the binding site for TNF-receptor mediated factors (TRAFs), a domain homologous but distinct from death domain 1 of typical death receptors and a PSD-binding domain.

Binding of neurotrophins is the primary mechanism by which Trk receptors are activated but the affinity and specificity of neurotrophins for Trk receptors is regulated by p75^{NTR}. For example, the association of p75^{NTR} with Trk receptors induces a conformation that has high affinity for NGF. Association of p75^{NTR} also enhances the discrimination of Trk for their preferred neurotrophin ligand (Barker, 2004; Lee et al., 2001; Meldolesi et al., 2000).

The activation of p75^{NTR} plays an important role in neuronal growth. Unliganded p75^{NTR} is an activator of RhoA which mediates the effects of CNS-derived myelin-based growth

FIGURE 16.1. Basic scheme of signaling. Signal transduction pathways are usually composed of four stages as indicated. After ligand binding, receptor becomes activated and intracellular part of activated receptor recruits adapters and modulators that may produce second messengers. Second messengers may involve activation of enzymes like kinases and phosphatases, and/or transcription factors. Finally, activation of transcription factors results in gene transcription, whereas signals not involving them mostly result in post-translational modification of existing proteins.

inhibitors (MGBIs) that include Nogo, myelin-associated glycoprotein (MAG1) and oligodendrocyte myelin glycoprotein (OMgP). The precise signaling mechanisms by which p75^{NTR}-Nogo complex inhibit neuronal growth remains unresolved. However, studies suggest that the binding of MGBIs to p75^{NTR}-Nogo complex enhances the association of Rho-GDI α (Rho-GDP dissociation inhibitor α) while NGF abolishes p75^{NTR}-Rho-GDI α interaction.

16.3.1.3. Ca^{2+} Signaling

Neurons communicate with each other (as well as with other non-neural cells) either via electrical (action potential) or

chemical (neurotrophins and other modulatory ligands) signals. In response to these signals, neurons alter their intracellular free Ca^{2+} levels. This rise in intracellular free Ca^{2+} serves as a ubiquitous second messenger signal to regulate a broad repertoire of neuronal function including axonal and dendritic growth and function, gene transcription, neurotransmitter release, and apoptosis (Berridge, 2005; Ross et al., 2005; DeCoster, 1995). Ca^{2+} can regulate this diverse array of function by virtue of the quantity of release (amplitude), where in the neuron it is release (spatial location) and for how long it was release (time). Under resting conditions, the cytoplasmic free Ca^{2+} in neurons is about 100 nM and upon neuronal activation cytoplasmic free Ca^{2+} increases to about 1–10 μ M. The Ca^{2+} that is used

for this cytoplasmic increase is mobilized either from external stores (extracellular space) following activation of ligand-gated channel (e.g. NMDA and P2X receptors), voltage-operated Ca^{2+} channels (L-type, T-type and N-type Ca^{2+} channels) or from internal stores (endoplasmic reticulum) via activation of inositol 1,4,5-trisphosphate receptors (InsP3R) and ryanodine receptors (RyR) (Berridge, 2005; Ross et al., 2005; DeCoster, 1995). The rise in cytoplasmic Ca^{2+} maybe sufficient to cause vesicles to fuse to plasma membrane and release their content into the synaptic cleft (neurotransmitter release), overload mitochondria and induce apoptosis, or activate transcription factors that result in gene expression. After the physiological task is completed, the influxed Ca^{2+} is removed from the cytoplasm by plasma membrane bound Ca^{2+} -ATPases (PMCA) and Na^{+} - Ca^{2+} exchangers. Ca^{2+} that are mobilized from the endoplasmic reticulum are returned to the stores via sarco(endo)plasmic reticulum Ca^{2+} -ATPase (SERCA).

16.3.2. Signaling in Physiological Events of CNS

While there are several interesting aspects of CNS physiology, we will restrain our discussion to signaling in two facets thereof, namely, neuronal plasticity (leading to memory formation) and myelination. While myelination is quite a segregated topic, plasticity and memory formation enjoy viciously overlapping signaling pathways (Matynia et al., 2001), for plasticity is indeed the basis of memory formation/consolidation.

16.3.2.1. Signaling in Neuronal Plasticity and Memory Formation

What is renovating in your brain right now as you are learning about signaling of memory formation, a fraction of which you will perhaps retain in your memory for years to come? The answer is neuronal plasticity, the key prelude to memory formation. It is a consequence of both, qualitative alteration in efficacy of synaptic transmission and quantitative alteration in synapse number due to synaptic growth.

16.3.2.1.1. Signaling in Generation of Short-Term Plasticity and Short-Term Memory

Short-term sensitization of a synapse can occur even in the absence of protein synthesis and is largely dependent on post-translational modification of existing proteins. Assessment of alteration in efficacy of synapses is often performed in laboratories by quantifying long-term potentiation (LTP) or long-term depression (LTD), the artificially induced forms of plasticity. LTP, reflecting short-term plasticity and short-term memory, is often referred to as the early or transient LTP (eLTP) which is induced by weak signals, such as a ringing bell. eLTP involves activation of cAMP and PKA in pre-synaptic neuron and activation of a set of kinases and phosphatases in the post-synaptic neuron that includes their signal dependent transportation to post-synaptic membrane.

In a pioneering effort back in 1976, Eric Kandel, Nobel Laureate for Physiology and Medicine in 2000, had delineated involvement of cAMP in regulation of synaptic transmitter release in giant neurons of *Aplysia* (Kandel, 2001). Subsequently it was elucidated that elevated level of cAMP broadens action potential by limiting certain K^{+} currents while enhancing Ca^{2+} influx into pre-synaptic terminal. In addition to cAMP, protein kinase A (PKA) inhibitors also block pre-synaptic short-term facilitation suggesting a role for this kinase in this process. Activation of PKA, incidentally, is also dependent on elevated cAMP level (Kandel, 2001). Once activated, PKA can regulate release of neurotransmitters and activity of ion channels thereby strengthening synaptic connections for the whole time course of short-term plasticity (Figure 16.2).

In the post-synaptic neuron, binding of the transmitter to its receptor facilitates a brief Ca^{2+} influx which sensitizes the Calcium/Calmodulin-dependent protein kinase II (CaMKII). Since CaMKII remains independently active after transient activation by Ca^{2+} (See Lisman et al., 2002 for more information), this kinase serves well to convert brief synaptic impulse into longer physiological signaling. In addition to its regulation with Ca^{2+} /Calmodulin, activity of CaMKII is enhanced by its binding with cytoplasmic C-terminus tail of NMDA receptor 2B subunit. This binding anchors the enzyme to the membrane, where it phosphorylates GluR1 thereby facilitating conductance of AMPA receptor and their insertion by an indirect mechanism. Physical transport of these receptors in and out of the synaptic membrane contributes to several forms of synaptic plasticity.

Phosphorylation of CaMKII is countered by a specific phosphatase, protein phosphatase 1 (PP1), which remains inactive due to PKA activity. Incidentally, it must be taken into account that PKA activity is not restricted to pre-synaptic cell only, but is also engaged in post-synaptic neuronal signaling. PKA inhibits PP1 activity by phosphorylating the regulatory protein inhibitor-1 (I-1). Protein phosphatase 2b (PP2b) dephosphorylates I-1 to activate PP1, which then attenuates CaMKII activity thereby culminating LTP (Blitzer, 2005). It is thus appropriate to reckon PP1 as the molecule of 'forgetfulness' (Silva and Josselyn, 2002).

16.3.2.1.2. Signaling in Generation of Long-Term Plasticity and Memory

Long-term plasticity and long-term memory essentially is an extended version of short-term plasticity and short-term memory. Both long-term and short-term forms of these processes are dependent on increase in synaptic strength, which in turn is manifestation of enhanced broadening of action potential and release of transmitter in both cases. However, the similarities end there. Subsequently, these processes are different in two aspects. First, long-term changes are contingent on new protein synthesis and secondly, long-term processes involve structural alterations in synapse number and structure (Bailey et al., 2004). In the following lines, we will delineate the signaling responsible for both these operations.

FIGURE 16.2. Signaling for memory formation. Short-term memory formation involves the activation of PKA, but no gene transcription. Activation of G-protein coupled receptors by excitatory stimuli activates adenylyl cyclase. This leads to the elevation of cAMP level, which subsequently activates PKA. Activated PKA undertakes modulation of channels thereby enhancing conductivity. However, prolonged/repeated activation of this system results in nuclear translocation of PKA, which is the central molecular basis of long-term memory formation. Activated PKA and MAPK activate transcription factor CREB-1 while suppressing the inhibitory CREB-2. Activated CREB-1 binds to CRE region in promoters of early genes like C/EBP. Interestingly, C/EBP itself is a transcription factor that subsequently teams up with CREB to express late memory genes.

Signaling Involved in New Protein Synthesis. We are by now aware of the fact that sensitization of pre-synaptic neurons (by excitatory moieties like 5-HT) elevates cAMP level, which in turn, activates PKA. Interestingly, for long-term memory formation this train of events, responsible for short-term processes, continues further as a conserved central signaling pathway of long-term information processing. PKA activates gene expression by phosphorylating the transcription factor cAMP responsive element binding protein (CREB1), a key 'memory molecule'. Once activated, CREB1 transactivates a set of early genes including two more important transcription factors, CAAT box/ enhancer binding protein (C/EBP) and activation factor (AF) (Kandel, 2001). These transcription factors subsequently regulate expression of important downstream memory genes (Figure 16.2).

However, activation of memory-enhancing genes is only half the tale. The other half involves suppression of memory-suppressing genes by a repressor isoform of CREB1, called CREB2. Interestingly, while one MAPK (ERK) acts to facilitate memory formation, yet another MAPK, called p38, acts a repressor of memory formation. Although exact basis of such inhibition is yet unknown, it has been proposed that p38-MAPK impedes memory formation indirectly by inhibiting activation of ERK (Sharma and Carew, 2004) (Figure 16.2).

In addition to CREB, nuclear factor kappaB (NF- κ B) is another architect of importance in facilitating long-term processes. NF- κ B p50:p65 is located in synapses of neurons and is engaged in Ca²⁺ responsive pathway. Additionally, it has been proposed that activation of NF- κ B p50:p65 is dependent on CaMKII activation (Meffert and Baltimore, 2005). As suggested

by impairment of spatial learning by error-prone p65-deficient mice, p65 is involved in long-term processes of information retention. We will hear a lot more about this dimeric transcription factor in neuroinflammation and neurodegeneration sections.

Signaling Involved in Synaptic Remodeling. Synaptic remodeling involved in long-term processes has two facets. Firstly, it involves activation of previously present 'silent' synapses and secondly, it involves engineering brand new synapses. Both ways, the process mainly involves redistribution of synaptic vesicle proteins to reinforce active zone components and more importantly, rearrangement of cytoskeleton. The latter forms the structural basis of increment in synaptic contact area and/or formation of new filopodia, many of which are morphological precursors for learning-associated new synapses (Bailey et al., 2004). In dendritic spines of neurons, LTP induction is greatest in spines with greatest F-actin content (Fukazawa et al., 2003) underscoring the importance of F-actin assembly in long-term processes. How is extracellular signal conveyed to achieve actin polymerization? In general, F-actin formation is greatly dependent on signal transduction by small GTPases of Rho family. In *Aplysia*, repeated pulses of 5-HT (capable of inducing long-term processes) selectively activates small GTPase Cdc42, but not Rho or Rac, through the PI3K and PLC pathways. Once activated Cdc42 activates downstream effectors PAK and N-WASP and initiates reorganization of the presynaptic actin network (Udo et al., 2005).

16.3.2.2. Signaling in Axonal Myelination

Myelination, the process of wrapping up byzantine axonal processes with a insulating coat of myelin synthesized by an unique glial population (Oligodendrocytes in CNS and Schwann cells in PNS), involves several receptor signaling pathways in both participating cells, i.e., axons as well as glia. In following lines, we will survey the steadily increasing knowledge base regarding two aspects of myelination; first, signals dictating selection of axons for myelination, and then, signals regulating thickness of myelin sheath. (See Sherman and Brophy, 2005 for additional aspects of myelination.)

16.3.2.2.1. Sorting the Axon to Wrap; Signaling in Both Parties

Foremost stages of axonal myelination are contingent on action of neurotrophins. Interestingly, NGF, the prototypical neurotrophin, promotes myelination by Schwann cells, but inhibits myelination by oligodendrocytes (Chan et al., 2004). This is particularly interesting as NGF manipulates myelination by engaging axonal, but not glial, TrkA receptors. How does NGF affect myelination? A previous section of this chapter has illuminated after-effects of ligand dependent engagement of Trk receptors. It is postulated that these signals converge in the nucleus and trigger expression of neuronal genes that modulate glial cells to myelinate. Potential representation of the second category includes small molecules like adenosine

that may act on glial purinergic receptors (Stevens et al., 2002) or other moieties such as neuroregulins (Taveggia et al., 2005), which are a family of receptor tyrosine kinases related to EGF and whose receptors (erbB/HER 2–4) are well expressed in myelinating glial cells.

However, NGF responsiveness is not the only event in axon selection for myelination as sensory C-fibers in PNS remain non-myelinated despite expressing TrkA receptor (thus being potentially capable of intercepting up NGF cues). Certain other neurotrophins may be involved. For example, GDNF stimulates the process at an early stage by regulating early stage Schwann cell function by activating PKA and PKC pathway (Iwase et al., 2005). Additionally, considering hindrance posed by NGF in oligodendrocytic myelination, signal transduction in this cell-type must be dependent on some yet unknown non-NGF mechanism. It has been proposed that by altering surface exhibition of certain 'wrap me'/'do not wrap me' signals, axon themselves act as determinants of their myelination (Coman et al., 2005).

16.3.2.2.2. Signals Regulating G-Ratio

The ratio of the axonal diameter divided by the diameter of the axon plus its myelin sheath is referred to as the G-ratio. Usually, the G-ratio is maintained between 0.6 and 0.7. The importance of this constancy lays in the fact that thickness of myelin wraps depend on axonal thickness and demonstrate proportionality. One of the main regulators of the myelin thickness is signal(s) induced by Neuregulin-ErbB system (Michailov et al., 2004). Additionally, neurotrophins like BDNF and neurotrophin p75^{NTR} are also thought to be involved in regulating myelin sheath thickness (Tolwani et al., 2004).

16.4. Signaling During Neuroinflammation

16.4.1. Neuroinflammation

Although inflammation is a self-defense operation, it may attain harmful proportions if not controlled strictly. Evolved as much as we are, human inflammatory system still gets into the overdrive mode in several instances and instead of being efficacious, creates havoc. Neuroinflammation is one such example. Unrestricted inflammatory response in CNS is now considered a root cause of several neurodegenerative diseases, as an overdose of inflammatory moieties tend to injure/ kill neurons.

16.4.1.1. Cells Involved

Considering CNS to be devoid of immune-surveillance has been one of the most coveted myths of biology. We now realize, CNS has its own share of immunological residents (microglia) and is also subjected to infiltration of peripheral immune-cells (macrophages, monocytes and T cells) during diseased states. Additionally, in pathologic brain, astrocytes and endothelial cells of BBB also show an upsurge in expres-

sion of immunological moieties. ‘Gliosis’ is the term commonly used to indicate such inflammatory status of glial cells, which by definition, refers to reactive populating of insulted area in brain or spinal cord by excess growth of glial cells. Reactive gliosis, a neuroinflammatory hallmark, is clinically manifested by enhanced expression of a battery of pro-inflammatory molecules like inducible nitric oxide synthase (iNOS), cyclooxygenase-2 (COX-2), certain adhesion molecules like ICAM and VCAM, and a plethora of pro-inflammatory cytokines like tumor necrosis factor- α (TNF- α) and interleukins (like IL-1, IL-6). In the following lines we shall concentrate on the pathways upregulating these gene products.

16.4.1.2. Inducers

Inducers for neuroinflammation may arise within the CNS (intrinsic) or may be introduced by external agencies (extrinsic). The major intrinsic trigger for neuroinflammation is a necrotic neuron, which tends to dissipate considerable amount of cellular junk around the dying cell, which trigger inflammation in adjacent glial cells. Additionally, pro-inflammatory cytokines, like TNF- α , IL-1 β , and IFN- γ , are other major intrinsic inducers of neuroinflammation. Furthermore, contact with certain peripheral inflammatory cells, which sneak into brain through a leaking blood brain barrier during diseases, often triggers inflammatory response in glial cells (Dasgupta et al., 2003).

On the other hand, extrinsic stimuli are often delivered by viruses and bacteria. Bacterial products like lipopolysaccharide (LPS) and DNA with motifs of unmethylated CpG dinucleotides are extremely potent inducers of neuroinflammation. Additionally, viruses themselves, or their products like retroviral coat protein gp41 and gp120, double stranded RNA, and transcription factors like Tat, also induce inflammatory responses in brain cells.

16.4.2. Signaling for Gliosis

16.4.2.1. Positive-Regulatory Signals

16.4.2.1.1. Activation of Pro-inflammatory Transcription Factors (TFs)

Among several TFs involved in mediating neuroinflammation, NF- κ B, CCAAT/enhancer-binding protein (C/EBP), activating protein (AP-1), STAT, and interferon regulatory factors (IRF) are the top five TFs that are required for transactivation of almost all pro-inflammatory molecules. Among five members of NF- κ B family, dimers of p50:p65 are the most important inflammatory mediators. Activated kinase pathway(s) phosphorylate p50:p65 arresting protein, inhibitory kappaB (I κ B) in the cytosol, thereby subjecting it for ubiquitination and subsequent proteosomal degradation. This liberates the p50:p65 heterodimer to enter the nucleus and bind kappaB elements in the target promoter (Li and Verma, 2002). Such targets include

almost every gene, whose products are known to be associated with neuroinflammation. C/EBP, a family of six basic leucine zippers, are involved in several cellular responses including, inflammation (Ramji and Foka, 2002). Among them C/EBP β and C/EBP δ , known to form homo- and heterodimers between themselves, occur most frequently in the neuro-inflammatory radar. Another basic leucine zipper TF is AP-1, which is mainly composed of Jun, Fos, and/or ATF dimers (see Hess et al., 2004 for more details). Leaving out STAT (subsequently discussed elaborately), IRFs are mainly recognized and named after their central role in mediating anti-viral responses. Also, several IRFs (like IRF-1) play an important role in neuroinflammation.

Activation of TFs is the culminating step of several signal transduction pathways, and requires upstream activity of various kinase pathways. Let's roll upwards.

16.4.2.1.2. MAP Kinase Pathway

All three MAP kinase pathways are involved in neuroinflammation in different combination depending on inducing signal and the final product. For example, for iNOS regulation in human astrocytes, both JNK and p38 pathways are recruited in response to IL-1 β . However, co-induction by IL-1 β along with IFN γ renders the JNK pathway redundant while the p38 pathway is utilized. Once, recruited, MAP kinase cascades ultimately convey inflammatory signal mainly by activating different TFs. Activation of JNK leads to phosphorylation of Jun, which then enters the nucleus to form AP-1 by dimerizing with Fos. Activation of the MEK-ERK cascade mostly activates C/EBP dimers, although activation of other TFs is not ruled out. On the other hand, the hypothesis of NF- κ B being downstream of p38 MAP kinase is controversial. In other instances, p38 also regulates TFs like C/EBP, ATF-2, and AP-1 (Figure 16.3B).

In addition to TFs, MAP Kinases may play certain non-canonical roles as well in inducing neuroinflammation. For example, p38 has been shown to phosphorylate Ser10 of Histone3 in promoter region of pro-inflammatory genes (Saccani et al., 2002). Such phosphorylation is postulated to be the epigenetic signature for facilitated docking of pro-inflammatory transcription factors like NF- κ B. Additionally, MAP kinases may regulate inflammatory gene expression by regulating certain co-activators.

16.4.2.1.3. JAK-STAT Pathway

While MAP kinases are serine/threonine cascades, the Janus kinase (JAK)-signal transducers and activators of transcription (STAT) pathway epitomizes tyrosine kinase signaling in gliosis. The JAK family is one of ten recognized families of non-receptor tyrosine kinases. Originally identified as the signaling pathway for interferons, JAK-STAT signaling is now known to mediate signals of various cytokines, growth factors and hormones. The basic biology of JAK-mediated signal transduction (Rawlings et al., 2004) is based on ligand-stimulated assembly of receptors

into an active complex followed by phosphorylation of the receptor-associated JAKs (JAK1, JAK2, and JAK3) and tyrosine kinase 2 (Tyk2). Subsequently, phosphorylated JAKs phosphorylate inactive cytosolic STATs, which in turn are activated to form

homo- or heterodimers. These dimers enter nucleus and bind specific regulatory sequences to activate or repress transcription of target genes (Figure 16.3A). During gliosis, this pathway primarily activates a set of genes including, iNOS, and COX-2.

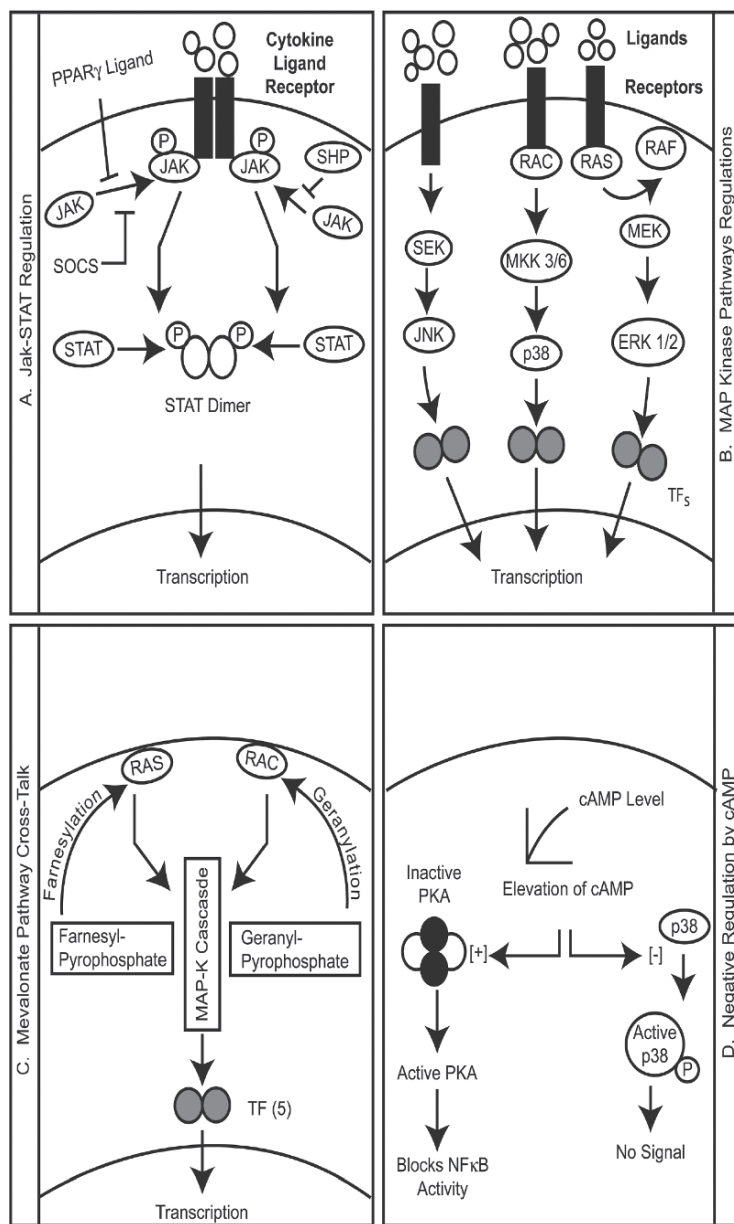

FIGURE 16.3. Various aspects of neuroinflammatory signaling. (A) Ligand-bound receptors auto-activate and then recruit and activate JAK. Subsequently, JAK phosphorylates STAT and facilitates the formation of STAT active dimer that can translocate to the nucleus and participate in gene transcription. Negative regulators of this pathway, like SHP, SOCS and many nuclear receptor ligands, inhibit phosphorylation of JAK and thereby defuse the pathway. (B) All three known MAP kinase pathways, as a common denominator, activate one or more transcription factors, which then mediate gene expression. However, MAP kinases may perform other roles not shown in this diagram. (C) Small G-proteins like Ras and Rac, which acts upstream of MAP-kinase pathways, are at times regulated by cross-talk with other normal biochemical pathways in cell. As shown here, geranylpyrophosphate and farnesylpyrophosphate intermediates of mevalonate cholesterol biosynthesis pathway. These intermediates modify Ras and Rac thereby activating them to induce further signals via MAP kinase pathways. (D) In glial cells, elevation of cAMP leads to the activation of PKA, which in this case, blocks the activation of proinflammatory transcription factors like NF- κ B. Elevated cAMP levels also inhibit p38 activity, thus blocking the activation of several transcription factors that function downstream of this kinase.

16.4.2.1.4. Small G-Protein Signaling

We have talked about activation of MAP kinases that subsequently activate TFs. Now, MAP kinases, unlike JAKs, do not get activated by receptor docking. Signals are relayed to MAP kinases from the receptors by an elite group of messengers called small G-proteins (SGP). Based on structural delineations, the SGP super-family is divided into five families; the Ras, Rho/Rac, Rab, Sar1/Arf, and Ran. These 20–30 KDa monomeric GTPases serve as molecular switches of signal transduction by shuttling between two interchangeable forms, the GTP bound active form and the GDP bound inactive form (Takai et al., 2001). During gliosis, the MEK-ERK cascade is sensitive to Ras-Raf activity. On the contrary, activation of MKK3/6, the upstream kinase for p38, is dependent on Rac activity.

How is the signal mediated by SGPs? If the signal originates from G-protein coupled receptors (GPCR), then SGPs may be activated either by signals originating from the classical heterotrimeric G-protein effectors or by activation of receptor tyrosine kinases. The exact mechanisms for these processes are not well understood. However, SGPs also trigger signaling events without involvement of GPCRs. SGPs, like Ras and Rac, are post-translationally modified by metabolites of mevalonate biochemical pathway. Non-saponifiable lipid isoprenoids like farnesyl- and geranylgeranyl-pyrophosphate, are biosynthesized in animals from acetyl-CoA via the mevalonate pathway. These isoprenoids covalently modify and thus modulate the biological activity of SGPs (Maltese, 1990). Upon isoprenylation, these G proteins become membrane-bound and transduce several intracellular signaling pathways leading to activation of MAP kinases (Pahan et al., 1997b) (Figure 16.3C).

16.4.2.1.5. Redox Signaling

Reactive oxygen species (ROS) are multi-potent diffusible molecules capable of carrying out several signal transduction processes in response to several extracellular stimuli. Consistent with their versatile cellular functions, ROS have been also shown to regulate expression of inflammatory products like, iNOS in different brain cells. Antioxidants, like N-acetyl cysteine (NAC), pyrrolidine dithiocarbamate (PDTC) and lycopene are potent inhibitors of inflammatory products in glial cells, thereby proclaiming a role of ROS in mediating gliosis.

Recently, NADPH oxidase has been identified as the ROS-producing molecule in activated glial cells (Pawate et al., 2004). Cytokine stimulation of astrocytes leads to rapid activation of NADPH oxidase and release of ROS followed by expression of pro-inflammatory products like, iNOS. Consistently, attenuated expression of iNOS is observed in primary astrocytes derived from gp91^{Phox}-deficient mice (Pawate et al., 2004). ROS are believed to regulate expression of pro-inflammatory gene products via NF- κ B. However, the involvement of other transcription factors in ROS-mediated gliosis cannot be ruled out.

16.4.2.1.6. Nitric Oxide Signaling

One of the unavoidable fall-outs of ROS generation is induction of iNOS, which enhances production of nitric oxide (NO) from glial and endothelial cells. NO, the popularly known vasorelaxant, also works as a neurotransmitter when produced in physiological quantities by neurons. However, in excess concentration, NO forms peroxynitrite (ONOO⁻), a neurotoxic mediator of neuroinflammation. The effects of peroxynitrite in immune regulation are exerted through nitrosylation of cell signaling messengers like cAMP, cGMP, G-protein, JAK/STAT or members of MAP kinase dependent signal transduction pathways (Guix et al., 2005). Nitration of cysteine residues of these proteins may inhibit or activate their functionality. Similar modifications may also manipulate activity of transcription factors like NF- κ B, thereby modulating gene expression and encouraging inflammatory outbursts.

16.4.2.1.7. Signaling by Toll-Like Receptors (TLRs)

TLRs are archetypal pattern recognition receptors of innate immune system found in several invertebrates and all vertebrates. Being transmembrane moieties, they recognize a variety of conserved patterns and motifs found in pathogenic entities, and thus serve as sensors of microbial invasion. Once engaged, TLRs generate a complex anti-pathogenic immune response in various cell types, including glial cells in brain. 10 TLRs have been identified in human so far (Konat et al., 2006). All of these possess a structural motif in their cytoplasmic tail [Toll/IL-1 receptor (TIR) domain], which forms the basis of signal transduction by these receptors (Barton and Medzhitov, 2004). Upon ligand binding, adaptor molecules like, MyD88, bind to these receptors and recruit the IL-1 receptor associated kinase (IRAK) leading to their phosphorylation. Phosphorylated IRAK transduces the message downstream and activates MAP kinases and transcription factors like NF- κ B. In brain, most of the known TLRs are expressed in brain immune cells, i.e., microglia and astrocytes (Bsibsi et al., 2002; Konat et al., 2006). Furthermore, exposure to specific ligands or certain cytokines induce a rapid upregulation of several TLRs in these cells. TLRs play an important role in mounting immune response in brain abscess as well as other CNS gram-positive infections. However, persistent TLR signaling, which may result from residual microbial products after CNS infection clearance, may potentially damage the brain (Konat et al., 2006).

16.4.2.2. Negative-Regulatory Signals

16.4.2.2.1. Activation of Protein Kinase A

We have already seen a contingency in functioning of cAMP and PKA in previous sections. During glial inflammation, expression of several cytokines and iNOS is dependent on the cAMP-PKA pathway. While expression of cytokines like IL-1 β is completely dependent on PKA, expression of pro-inflammatory moieties, like iNOS, are partially dependent on this enzyme (Woo et al., 2004). Despite its partial role, activation of this

pathway adequately hinders expression of iNOS (Pahan et al., 1997a). Anti-inflammatory agents like, KL-1037 and N-acyetyl-O-methyl-dopamine, prohibit microglial activation by activating the PKA pathway (Kim et al., 2004, Cho et al., 2001). Taken together, PKA pathway may be considered as a general inhibitory pathway with regard to glial activation (Figure 16.3D). How does PKA block the pro-inflammatory response in glial cells? Recently, it has been shown that cAMP inhibits the activation of p38 MAP kinase in rat primary astrocytes and C6 glial cells (Won et al., 2004). As we have seen in the previous section the p38 MAP kinase plays a pivotal role in glial inflammation. Thus, blocking this kinase will definitely destabilize potential pro-inflammatory signaling intensions (Figure 16.3D).

16.4.2.2.2. Activation of SOCS

In order to counter pro-inflammatory signaling pathways, cells employ a family of proteins called suppressors of cytokine signaling (SOCS). Due to their ability to regulate and subdue a pro-inflammatory signal, these proteins are now considered important regulators of normal immune physiology and immune disease (Leroith and Nissley, 2005). In general, SOCS are present in cells at very low levels. However, they are rapidly transcribed upon exposure of cells to pro-inflammatory stimuli. SOCS can negatively regulate the response of immune cells either by inhibiting the activity of JAK or by competing with signaling molecules for binding to the phosphorylated receptor. Moreover, activators of nuclear hormone receptor PPAR- γ , induce the transcription of SOCS1 and SOCS3 to inhibit the activity of JAK1 and JAK2 in rat primary astrocytes (Park et al., 2003). Both SOCS1 and SOCS3 are capable of binding JAKs to suppress their tyrosine kinase activity. Therefore, PPAR- γ activators reduce the phosphorylation of STAT1 and STAT3 and attenuate pro-inflammatory signals in activated glial cells. These results suggest that up-regulation of SOCS may represent a critical step for suppressing glial inflammation via negative regulation of the JAK-STAT pathway (Figure 16.3A).

16.4.2.2.3. Nuclear Receptor Ligands

Nuclear receptors (NR) are evolutionary conserved lipophilic ligand-regulated transcription factors that control gene expression. NR ligands (NRL) recruit coactivators to the DNA-bound NR thereby transactivating target genes. But we are talking about repression and not transactivation. So how are NRs involved in repression? In the context of neuroinflammation, it is now clear that NRLs repress gene transcription independent of nuclear receptor itself. For example, gemfibrozil, a ligand for peroxisome proliferator-activated receptor- α (PPAR- α), inhibits cytokine-induced iNOS expression in human astrocytes independent of PPAR- α (Pahan et al., 2002). Along similar lines, 15-deoxy-12, 14-PGJ2 (15d-PGJ2), a ligand for PPAR- γ , attenuates (LPS + IFN- γ)-induced expression of iNOS in rat primary astrocytes independent of the PPAR- γ itself (Giri et al., 2004). Recently, ligands for other NR such as

RAR and RXR have been also shown to suppress the expression of inflammatory products independent of NR (Xu et al., 2005, Royal et al., 2004).

How may NRLs repress iNOS without actually involving the NR? Gemfibrozil, the PPAR- α ligand, strongly inhibited (IL-1 β + IFN- γ)-induced activation of NF- κ B, AP-1, and C/EBP β but not that of STAT-GAS in human astroglial cells (Pahan et al., 2002). Furthermore, 15d-PGJ2 inhibits NF- κ B pathway at multiple points (Giri et al., 2004). Blocking of NF- κ B and other TFs is indeed a handy mode of shutting down stimulus-induced response in a short period of time. Additionally, few mechanisms have been offered to explain the blocking effect of NRLs on pro-inflammatory TFs. PPAR- γ ligands, 15d-PGJ2 and rosiglitazone, reduce phosphorylation of JAK-STAT pathway in activated rat astroglia and microglia thereby leading to the suppression of JAK-STAT-dependent inflammatory responses (Park et al., 2003) (Figure 16.3A). This blockage is not contingent on PPAR- γ and is mediated by rapid transcription of suppressor of cytokine signaling (SOCS) 1 and 3. Additionally, SHP-2 is also involved in the anti-inflammatory action of NRLs. NRL treatment was shown to phosphorylate SHP2 within minutes. As phosphorylated SHP2 dephosphorylates JAK, this creates yet another avenue of blocking the JAK-STAT pathway.

16.4.2.2.4. IL-10 and IL-13 Signaling

IL-10 and IL-13 are anti-inflammatory cytokines. In CNS, systemic inflammation is mediated by expression of these cytokines along with pro-inflammatory ones. The purpose of expressing pro- and anti-inflammatory molecules at the same time is to provide the system with self-antidotes. Similarly, IL-10 knock-out mice demonstrate elevated production of inflammatory gene products in the brain in comparison to their wild-type littermates during encephalitis. IL-13 on the other hand, induces death of activated microglia (Yang et al., 2002), thereby restricting inflammatory output of these cells. Such effect of IL-13 is mimicked by yet another anti-inflammatory cytokine, IL-4. This comes as no surprise since IL-13R α 1-IL-4R α complex constitutes a receptor for both IL-4 and IL-13 (Hershey, 2003).

How do these anti-inflammatory cytokines work? Essentially, they tend to inhibit biosynthesis of pro-inflammatory cytokines by stimulating biosynthesis of pro-inflammatory cytokine inhibitors like soluble receptors (Burger and Dayer, 1995). Furthermore, they also intercept signals arising from pro-inflammatory receptors-ligand complexes. For example, pro-inflammatory cytokines kick-start the breakdown of plasma-membrane sphingomyelin into ceramide, the second messenger in sphingomyelin pathway, which subsequently acts on downstream JNK pathway. On the other hand, IL-10 and IL-13 inhibit pro-inflammatory cytokine-mediated breakdown of sphingomyelin to ceramide thereby interrupting further pro-inflammatory signaling. This inhibitory signal is mediated via activation of phosphatidylinositol (PI) 3-kinase (Pahan et al., 2000).

16.5. Signaling During Neurodegeneration

Comprehension of the current topic lies in apprehending signaling in neuronal cells. Unlike glial cells, which are threatened with neurodegenerative toxins, neurons tend to face stiff challenges by them. In a neurodegenerative milieu, a particular neuron may undertake signaling to die, or to resist the culmination, or both. To keep our mind clear, we shall focus only on anti-survival signals leading to death.

16.5.1. Neurodegeneration

16.5.1.1. Apoptosis in Neurons

During development, programmed cell death is a common norm in developing neurons. However, the intrinsic pro-apoptotic pathways are obliterated as neurons mature. Thus, mere withdrawal of trophic factors does not suffice in inducing their death. Additionally, a genuine apoptotic signal is required for onset of self-suicide process in neurons. Specific gene-products undertake the apoptotic task in different types of neurons and different stimuli may induce distinct apoptotic pathways in them (Pettmann and Henderson, 1998).

However, it is important to acknowledge that apoptosis is not the only means for neurons to die. Death of adult neurons in response to pathological challenges also occurs by necrosis, the unregulated cell death mechanism. Necrosis is mediated by increase in intracellular calcium that catalyses activation of Ca^{2+} -dependent cystine proteases like, cathepsins and calpains, which primarily compromise lysosomal integrity. Subsequently, these cystine proteases in the company of released lysosomal enzymes dismantle structural network of neuron. Additionally, the intracellular pH also plays a major role in necrosis (Syntichaki and Tavernarakis, 2003).

Let us get back to apoptosis and start with its inducers.

16.5.1.2. Inducers (Neurotoxins)

Depending on their origin, inducers of neuronal apoptosis can be divided into two categories - extrinsic and intrinsic. Extrinsic inducers are generally of viral or bacterial origin. Viral coat protein gp120, and transcription factors, like, Tat, induce neurodegeneration are often at the root of viral neuropathies like HIV-associated dementia. Similarly, bacterial products like LPS derived from *Salmonella* has been shown to be neurotoxic (Johansson et al., 2005). Certain other extrinsic conditions leading to neuronal apoptosis include hypoxia, UV radiation, and exposure to steroids.

Among intrinsic inducers, several neurotoxins are generated by inflamed glia, which includes excitotoxins like, kainate and glutamate, peroxynitrite radical, and cytokines. Among cytokines, members of the TNF superfamily are major rogues. FAS ligand (FASL/CD95L) and TNF-related apoptosis inducing ligand (TRAIL) are most noteworthy in this regard where TNF- α itself has a controversial role (Saha and Pahan, 2003).

Additionally, several misfolded and/or mutated cellular proteins like protease resistance Prion (PrP^{res}) (Prion disease), Parkin (Parkinson disease), Huntington (Huntington's disease), and amyloid- β (Alzheimer's disease) also cause neurodegeneration. Other intrinsic inducers include intracellular changes like, genotoxic damage, misbalance of intracellular Ca^{2+} and anioikis.

Several of these inducers (like FASL) induce neuronal apoptosis directly while others induce it indirectly (like LPS) via various mechanisms. It is interesting to note that there are several common inducers of neuroinflammation and neurodegeneration. Considering such diverse cellular response from same inducer in different brain cells, the diversity of signaling events in brain cells is quite apparent.

16.5.1.3. Neuronal Receptors

Receptors mediating neuronal apoptosis may be grouped in two types—dependence receptors and non-dependence receptors.

16.5.1.3.1. Dependence Receptors

These are a group of surface receptors that transduce two completely different sets of intracellular signals. In the presence of their respective ligand, these receptors generate a pro-survival signal. But in the absence of ligand, these receptors trigger a pro-apoptotic signal. Thus, survival of the cell is dependent on constant availability of the ligand and hence the receptors have been named as 'dependence' receptors (Mehlen and Bredesen, 2004). These receptors form ligand-dependent complexes that include specific caspases in inactive form. Absence of ligand leads to activation of caspase(s), which then cleaves the receptor itself, releasing a pro-apoptotic peptide fragment from it. p75^{NTR} was described as one of the earliest dependence receptors (Barrett and Bartlett, 1994). Moreover, several receptors, like DCC (Deleted in Colorectal Cancer) and Unc5H2, have been described as dependence receptors playing a major role in neurogenesis.

16.5.1.3.2. Non-Dependence Receptors:

These receptors are straightforward death-receptors without any ambiguity. The best examples of this category applicable to most neuronal types belong to TNF-R family and include TNFR1 and Apoptosis antigen (APO1/Fas/CD95). Ligation of these receptors competently induces death in neurons. In the following lines, we will expand on signaling pathways triggered by these receptors.

16.5.2. Activation of Anti-Survival Pathways

Two pathways lead to apoptosis in mature neurons; the intrinsic mitochondria-dependent pathway and the death receptor-induced extrinsic (mitochondria-independent) pathway. These pathways seldom function exclusively and often converge with each other.

16.5.2.1. Mitochondria-Dependent Pathways

Mitochondrion is one of the most multi-faceted cellular organelle that is involved in energy generation, calcium buffering and regulation of apoptosis. In a happy cell, the mitochondria remain intact and prohibit apoptosis by sequestering a myriad of pro-apoptotic molecules within itself. However, as an apoptotic signal triggers the mitochondria-dependent apoptosis pathway, mitochondria undergo structural changes to become a punctuated and leaky bag of pro-apoptotic molecules.

16.5.2.1.1. Mitochondrial Fission

Mitochondria undergo frequent fission and fusion (Bereiter-Hahn and Voth, 1994), a fact largely understated in cell biology textbooks. A balance between these two processes serves to maintain normal mitochondrial tubular network and thus manifests normal cellular functions. However, during apoptosis onset, mitochondria undergo rapid and frequent rounds of fission thereby generating fragmented punctiform organelles of various sizes. This sets up the stage for apoptosis by leading to mitochondrial DNA loss, respiratory imbalance and ROS generation to alarming proportions (Yaffe, 1999).

16.5.2.1.2. Mitochondrial Leakage

Injurious signal(s) induce translocation of BH3-members of Bcl-2 family (Bim, Bid, Puma, Bad, Noxa, and BMF1) to mitochondrial membrane where they permeabilize it by formation of 'pores' in the outer membrane ('mitochondrial permeability transition'). This leads to cytosolic release of pro-apoptotic molecules cytochrome C, SMAC/DIABLO, apoptosis-inducing factor (AIF), endonuclease G (EndoG), and high temperature requirement serine protease 2 (HTRA2/OMI). Once in the cytoplasm, cytochrome C interacts with cytosolic apoptotic peptidase activating factor-1 (APAF1) resulting in oligomerization of the later. This complex is subsequently called the 'apoptosome' as it binds procaspase-9 and results in its auto-activation to form active caspase-9. The apoptosome complex further mediates downstream caspase activation (Figure 16.4).

Other mitochondrial 'leaked' proteins serve apoptosis from a different angle. SMAC/DIABLO binds and sequesters anti-apoptotic IAP proteins, which otherwise inhibit caspase activity. Similarly, HTRA2 interacts with X-linked IAP (XIAP) thereby interfering with its caspase inhibitory activities. HTRA2 also triggers DNA fragmentation. Also, DNA fragmentation and chromatin condensation is undertaken by the flavoprotein AIF, which interestingly acts without aid of caspases. In addition to HTRA2 and AIF, nuclear DNA also endures direct cleavage activity by the sequence-unspecific DNAase EndoG. (See Lossi and Merighi, 2003 for more details.)

16.5.2.2. Mitochondria-Independent Pathways

Activation of the core apoptotic machinery in mature neurons requires *de novo* transcription and this is not dependent on mitochondria (Figure 16.4). These pathways are discussed below.

16.5.2.2.1. p53 Pathway

p53, a tetrameric transcription factor, has been implicated in neuronal death in several neurodegenerative diseases, including, stroke, AD, PD, and ALS. p53 activity in neurons is upregulated in response to several neurodegenerative stimuli like hypoxic shock, excitotoxicity, DNA damage, and oxidative stress. Such activation is contingent on any of/all three signal-dependent post-translational modifications: phosphorylation (primarily at the N-terminal end), acetylation (primarily at the C-terminal end) and poly-(ADP)-ribosylation.

Once activated, p53 transactivates an array of pro-apoptotic genes products including the death receptors like Fas/CD95, members of mitochondrial apoptotic pathway like, Bax, Puma, Siva, Noxa, Peg3, and Apaf-1 (Culmsee and Mattson, 2005). Furthermore, p53 manipulates several transcription factors, thereby interfering with their normal job. For example, p53 activation blocks NF- κ B activity, which in neurons mediates transcription of several pro-survival gene-products. In addition to such nuclear role, p53 can directly trigger synaptic apoptosis by translocating to mitochondria in company of Bax and inducing mitochondrial permeability transition.

16.5.2.2.2. E2F Pathway

Early gene 2 factor (E2F) is a transcription factor that triggers transcription of many genes involved in DNA replication and cell growth control in a dividing cell and acts downstream of several important signaling cascades that regulate cell cycle. E2F remains inactive during early G1 phase of cell-cycle due to sequestering action of hypophosphorylated retinoblastoma (Rb) protein. However, during late G1 phase, hyperphosphorylation of Rb inactivates it, thereby permitting E2F activity whose transcription products drive the cell through cell-cycle routines (Stevaux and Dyson, 2002).

But in post-mitotic neurons, pro-apoptotic stimuli-induced E2F activation triggers core apoptotic machinery (Greene et al., 2004). E2F1 down-regulates the expression of anti-apoptotic factors while upregulating several pro-apoptotic genes like, *apaf1*, *casp 3*, *casp 7*, and *siva*. Furthermore, E2F1 expression leads to the stabilization of p53. But most interestingly, E2F triggers neuronal apoptosis by derepressing cell-cycle regulators (e.g. cyclins and cyclin-dependent kinases) in post-mitotic cells.

16.5.2.2.3. Sphingomyelin-Ceramide Pathway

Ceramide, a lipid second messenger, refers to a family of naturally occurring N-acylated sphingosines. It is generated by the activity of sphingomyelinase (SMase) that breaks sphingomyelin to yield ceramide and phosphocholine. The most common effects of eliciting the sphingomyelin-ceramide pathway are either differentiation or death. Although ceramide at low concentration induces neuronal differentiation, yet non-physiological dose of ceramide generated in a diseased CNS for a prolonged period, induce neuronal apoptosis. Toxic level of ceramide is induced in neurons in response to HIV-1 gp120 and fibrillar A β , where neutral SMase, but not the acidic one, plays pivotal role in

FIGURE 16.4. Pathways of neurodegeneration. Mitochondria-independent pathways usually arise from receptors with death domain (like TNF-R and FAS). Activation of these receptors leads to activation of pro-apoptotic transcription factor like c-Jun, which mediates the expression of a range of pro-apoptotic gene products. On the other hand, the mitochondria-dependent pathway relies on the permeability transition of its membrane, which leads to cytoplasmic release of several pro-apoptotic molecules. Among them, cytochrome C forms the lethal apoptosome complex by binding with cytosolic APF1 and caspase 9. This complex cleaves and activates down-stream caspases thereby ensuring apoptosis. Furthermore, there is ample crosstalk between these two pathways. For example, activation of pro-caspase 8 by ligand-bound death receptors leads to cleavage of Bid to tBid. Along with jBid, formed due to JNK activity, tBid attaches to mitochondrial membrane and form pores to manifest transition in permeability. The survival pathway is shown to appreciate the fact that, neuronal fate due to an insult is often the result of the prevailing pathway amongst ones mediating death and life.

ceramide generation (Jana and Pahan, 2004a,b). Although the mechanisms of ceramide-induced cell death is not fully understood, yet they appear to involve a number of signal transduction pathways, including proline-directed kinases, phosphatases, phospholipases, transcription factors, and caspases (Goswami and Dawson, 2000).

16.5.2.2.4. HAT-HDAC Misbalance

Histone acetyltransferases (HATs) and histone deacetylases (HDACs) represent two enzyme classes that, respectively, catalyze forward and backward reaction kinetics of lysine residue acetylation of nucleosomal histones and various transcription

factors. In a normal neuron, enzymatic undertakings of HAT and HDAC remain stoichiometrically balanced that in turn confers stability to the cellular homeostasis by coordinating gene expression and repression on both temporal and spatial basis (Saha and Pahan, 2005). Such equilibrium manifests neuronal homeostasis and is responsible for normal neuronal functions like, long-term potentiation, learning and memory.

However, during neurodegenerative conditions, the neuronal acetylation homeostasis is profoundly impaired. Such impairment is primarily manifested by comprehensive loss of HATs like CBP during various neurodegenerative challenges. However, HDAC protein level does not alter during neurodegeneration. Thus, at the cost of HATs' loss-of-dosage,

HDACs attain facilitated gain-of-function, thereby unsettling the acetylation homeostasis. At this stage, transcription of pro-survival genes is profoundly repressed due to collapsed histone gates at their promoter regions. Furthermore, several transcription factors like CREB, NF- κ B, Sp1, and HIF fail to perform their pro-survival transcription duties as all these TFs require to be acetylated for activation.

16.5.2.2.5. A Question to Ponder: Is NF- κ B Pro-apoptotic?

NF- κ B is critical transcription factor in neurodegeneration. It is a family of five TFs (Li and Verma, 2002) which can dimerize in various combinations amongst themselves leading to regulation of anti-apoptotic well as pro-apoptotic gene products (Barkett and Gilmore, 1999). Additionally, it also up-regulates inflammatory gene products as well. With activities spread out at extremes, there is little surprise in the decade old controversy regarding the actual role of NF- κ B in neurodegeneration. It is now being accepted that within neurons, NF- κ B acts as a pro-survival agent and is responsible for upregulation of survival ensuring gene-products like MnSOD, Bcl-2, Bcl-X_L, and IAPs (Mattson and Camandola, 2001). However, NF- κ B becomes the devil's advocate in glia, where it up-regulates neurotoxic and/or pro-inflammatory molecules, like iNOS, interleukins, chemokines (e.g. SDF-1 α) and excitatory products. If both statements are true, then is NF- κ B neurotoxic or neuroprotective? The debate goes on.

16.6. Signaling During Neuroregeneration

Ramon y Cajal had observed that while PNS tends to repair itself after injury, the CNS does not regenerate. He had concluded from his observations *in vivo* that CNS axons tend not to grow because of certain barriers present within the CNS. He had even suggested that these inhibitors are present in the white matter (myelin). Today, we realize that there are two main obstructions: myelin inhibitors and glial scars. After injury, certain inhibitors displayed on oligodendroglial plasma membrane generate inhibitory signals, which when perceived by an axon blocks its regeneration. Ultimately, scar tissue is formed in the area and regeneration is physically intercepted. However, spontaneous regeneration is manifested in some part of brain and in spinal cord due to amalgamation of several pro-growth signals. In the following lines, we will first talk about inhibitory signals and then about signals that promote regeneration.

16.6.1. Signals Blocking Axonal Regeneration

It is not the lack of neurotrophins, rather the presence of regeneration inhibitors in myelin and glial scars that effectively negate axonal regrowth (McGee and Strittmatter, 2003). Several myelin-derived proteins have been identified as components of CNS myelin, which prevents axonal regeneration

in the adult CNS. These inhibitors interact with their neuronal receptors to hamper axonal regeneration.

16.6.1.1. Inhibitor Trio in Myelin: Nogo, Mag, and Omgp

Three different myelin proteins have been identified as of now that are strong inhibitors of axonal growth (Schwab, 2004) (Figure 16.5).

Nogo, named by Martin Schwab of Zurich University, is a member of the endoplasmic reticulum associated protein family, reticulon. Despite being associated with endoplasmic reticulum of oligodendrocytes, Nogo-A is also exhibited on the surface and mediates growth cone collapse (Fournier et al., 2002).

Myelin-associated glycoprotein (Mag), belonging to immunoglobulin superfamily, is a potent inhibitor of post-mitotic neuronal outgrowth. There are two isoforms of this inhibitor that differ only in their cytoplasmic domain. Ability of Mag to bind sialic acid, although not essential for its inhibitory effect, potentiates it nonetheless (De Bellard and Filbin, 1999).

The third and most recent inhibitor is oligodendrocyte myelin glycoprotein (Omgp) (Vourc'h and Andres, 2004). Omgp is linked to outer leaflet of plasma membrane by a GPI-linkage and contains domains of leucine-rich repeats and serine/threonine repeats. Like Nogo and Mag, Omgp induces growth cone collapse and inhibits neurite outgrowth.

In addition to myelin, inhibitory signals also arise from glial scars. Proteoglycans are the main culprit in this regard. Additionally, certain proteins present in the scar, like ephrin-B2 and Sema3, also repel the growth cone (Silver and Miller, 2004).

16.6.1.2. Inhibitory Signaling from Receptor Trio: NgR-Lingo1-p75^{NTR}

It is remarkable that above mentioned all three myelin inhibitory proteins, without any significant domain or sequence similarity, bind and activate a common axonal multi-protein complex. This receptor complex is made up of the ligand binding Nogo-66 receptor (NgR1) and two binding partners responsible for triggering signal transduction, p75^{NTR} and Leucine-rich-repeat and Ig domain containing Nogo-receptor interacting protein-1 (Lingo-1). It is now believed that owing to functional redundancy, presence of any one of the three myelin inhibitory ligands can trigger inhibitory signal(s) through the axonal receptor complex (Filbin, 2003, McGee and Strittmatter, 2003) (Figure 16.5).

After ligand binding of NgR, further neuronal intracellular signal transduction requires either or both p75^{NTR} and Lingo as NgR does not traverse the plasma membrane and is linked to its outer leaflet by GPI-linkage. In both cases, the small GTPase, RhoA is activated, which subsequently mediates the signal via Rho kinase (ROCK) (Filbin, 2003) to cause growth cone collapse by enhancing retrograde F-actin flow (Dickson, 2001) (Figure 16.5). Recently, one more receptor has been described that participates in NgR complex signaling (Shao et al., 2005). Named TAJ/TROY, this orphan receptor belongs to

FIGURE 16.5. Pathways of neuroregeneration. Regeneration in the CNS is actively blocked by inhibitors expressed on the oligodendroglial membrane (Nogo, Mag and Omgp). All these inhibitors act on the Nogo66 receptor (NgR), which lacks a cytoplasmic tail. Further signal is conducted from NgR by either or both p75NTR and Lingo. In every case, the Rho GTPase is activated, which alters cytoskeletal arrangement via ROCK and other downstream effectors. However, priming of neurons with neurotrophins results in upregulation of polyamines, which potentially can prohibit the inhibitory effects of NgR complex signaling. Upregulation of polyamines in this case has been shown to be dependent on the cAMP-PKA pathway.

the TNF-superfamily and can functionally replace p75^{NTR} in the NgR complex to activate RhoA in the presence of myelin inhibitors.

16.6.2. Signals Inducing Axonal Regeneration

Neurotrophins can prime neurons for regeneration. They elevate cAMP in neurons in the absence of inhibitory signals, and this elevation sufficiently over-rides any subsequent inhibitory signals. *In vivo*, crushed DRG axons have been shown to regenerate into spinal cord by application of neurotrophins (Ramer et al., 2000). Interestingly, effects of neurotrophins, in most cases, occur through Trk receptor, while inhibitory effects are mediated through p75^{NTR}.

Events downstream of cAMP elevation occur in two phases - transcription-independent and transcription-dependent. In the first phase, PKA is activated which is believed to levy a direct effect on the cytoskeleton via Rho GTPase. The second phase

begins in a PKA-sensitive manner, but very soon manifests insensitivity to PKA. One of the most important targets of this pathway is the *arg1* gene, whose product (Arginase1) is a key enzyme in biosynthesis of polyamines. Generation of polyamines is the molecular mechanism of this pathway in countering inhibitory signals (Filbin, 2003) (Figure 16.5). Polyamines may exert their effects by influencing chromatin structure and transcription and/or influencing the cytoskeleton directly. They may also influence ion conductance across the axonal membrane.

Summary

Although not every dimension of CNS cellular signaling is covered in entirety due to restriction of publisher's space and reader's patience, yet sincere attempt has been made to introduce every known major signal transduction pathway

in CNS. Further reading from referred literature is highly recommended to readers willing to comprehend every known frontier of Cajal's 'epic love story'.

Review Questions/Problems

- Neurotrophins are employed for regulation and/or maintenance of axonal growth, dendritic pruning and synaptic refinements. List receptors for neurotrophins and mechanisms by which neurotrophin-receptor complexes become internalized.
- Three Trk receptor tyrosine kinases and four neurotrophins have been identified in the brain. How is affinity and specificity of neurotrophins for Trk receptors regulated?
- Ca^{2+} regulates a wide array of neuronal functions. How can this single ion regulate such a diverse functions as neuronal functions, ranging from neurite outgrowth, synaptic plasticity, transmitter release, etc.?
- Ca^{2+} is mobilized from two pools for elevating intracellular levels: the extracellular space and from intracellular endoplasmic reticulum (ER). Give examples ion channels on the plasma and the ER membranes that are used for mobilizing Ca^{2+} .
- After conveying a signal, intracellular Ca^{2+} levels must be restored to resting (basal) levels intracellular levels: Give examples of proteins (pump) on plasma and ER membranes that are used to lower intracellular Ca^{2+} levels.
- Which of the following signaling pathways is expected to antagonize the activation of mitogen-activated protein (MAP) kinase in brain cells?
 - JNK signaling
 - cGMP signaling
 - cAMP signaling
 - Akt signaling
 - JAK signaling
- Which of the following signaling pathways will be upregulated in microglia after stimulation with interferon- γ ?
 - cAMP-PKA pathway
 - cGMP-PKG pathway
 - JAK-STAT pathway
 - PI-3 kinase-Akt pathway
 - TLR4 pathway
- Multiple sclerosis (MS) is the most common human demyelinating disorder of the CNS. The expression of some genes may increase in the CNS of patients with MS. Identify those genes.
 - MOG
 - MBP
 - MAG
 - Nogo
 - PLP
- Alzheimer's disease (AD) is the most common neurodegenerative disease in which a particular set of neurons undergoes apoptotic cell death. Identify a signaling pathway that may attenuate neuronal apoptosis in patients with AD.
 - JNK signaling
 - p38 MAP kinase signaling
 - bcl2 signaling
 - Rho kinase signaling
 - Ceramide signaling
- In normal human brain, cells are equipped to counteract inflammatory signaling transduced by proinflammatory cytokines. Which one of the following molecules is expected to counteract such inflammatory signaling?
 - Ras signaling
 - Rac signaling
 - SOCS signaling
 - Nitric oxide signaling
 - Rho kinase signaling
- One of the following molecules should play an active role in transcriptional upregulation of memory genes in the CNS. Identify that molecule.
 - CREB
 - bad
 - bax
 - HDAC
 - Lingo
- During glial activation, microglia release superoxide that may lead to oxidative stress in the CNS. Which one of the following enzymes should be actively involved in producing superoxide radicals during microglial activation?
 - NADPH oxidase
 - SOD
 - Catalase
 - Acyl-CoA oxidase
 - Glucose oxidase
- What is nuclear factor- κB (NF- κB)? Describe the status of NF- κB in normal brain cells. What are the possible signaling mechanisms for the activation of NF- κB ? How is the activation of NF- κB related to neuroinflammatory diseases like MS and meningitis?
- What is a mitogen? How do the mitogens generally signal for the abnormal cell growth? How can you possibly inhibit mitogen-induced abnormal cell growth?
- Is mitogen-induced signaling involved in the pathogenesis of brain cancer? If yes, then explain with possible reasons and therapeutic targets.

Neurodegeneration

Serge Przedborski

Keywords Alzheimer's disease; Amyotrophic lateral sclerosis; Creutzfeldt-Jakob disease; Huntington's disease; Multiple sclerosis; Parkinson's disease; Prion diseases; Striatonigral degeneration; Synucleinopathies; Tauopathies

17.1. Introduction

An examination of the literature indicates that since 1982 the term *neurodegeneration* appears in the title of over 1280 indexed publications. Neurodegeneration is a mentioned topic of virtually all neurological science textbooks. Thus, it is safe to assume that the meaning of the word *neurodegeneration* is universally understood. Most relevant textbooks however will not actually define neurodegeneration but will discuss the issue in bits and pieces as part of the discussion of various diseases of the nervous system rather than as a single chapter. As previously discussed (Przedborski et al., 2003), neurodegeneration is composed of the prefix “neuro-,” which denotes relationship to a nerve or the nervous system (<http://tropmed.org/dictionary/coverpage9.htm>) and of “-degeneration,” which here is synonymous of devolution, meaning a process of declining from a higher to a lower level of effective power, vitality or essential quality (<http://www.wordreference.com>). Thus, neurodegeneration is any pathological condition in which the nervous system or nerve cell (i.e. neuron) loses its function, structure, or both. On a medical point of view however, the term neurodegeneration is used in a more restricted sense. Typically, it represents a large group of heterogeneous disorders in which affected neurons belong to specific subtypes, within specific anatomofunctional territories of the nervous system. Often, but not always, neurodegenerative diseases arise for unknown reasons and progress in a relentless manner. Within the context of this definition diseases of the nervous system can be catalogued into three broad categories: (i) pathologies which are restricted to the nervous system and which are *primary neuronal* diseases (i.e. neurodegenerative diseases *per se*); (ii) pathologies which are restricted to the nervous system but are not *primary neuronal* diseases, such as brain neoplasm or cerebral edema and hemorrhage; and (iii) pathologies provoked by systemic noxious factors which damage the nervous system, such cardiovascular arrest, poison, or

infections. Based on this simple categorization, hundreds of disorders of the nervous system including Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD), and amyotrophic lateral sclerosis (ALS) clearly fulfill the criteria of neurodegenerative disorder and are unanimously regarded as such. Aside from these unambiguous neurodegenerative diseases, others such as essential tremor, torsion dystonia, Tourette's syndrome, or schizophrenia represent an interesting nosological challenge, as they do not show any distinct neuronal loss. Perhaps they have been traditionally included in this category because they are chronic diseases of the nervous system with an unknown cause. Finally, diseases such as multiple sclerosis (MS) also represent a perplexing situation. Conventionally, MS has been linked to pathology of the myelin that ensheath neuronal axons and not of the neuron *per se*. Several experts, however, have argued that MS is not only a demyelinating disease but also a disease where the neurons die due to a destruction of their axons. Worth noting, long-term disability in MS has a higher correlation with axonal damage than with the degree of demyelination (Bjartmar et al., 2003). For these reasons, several scientific authorities now regard MS as a neurodegenerative disease.

17.2. Frequency, Lifespan, and Co-Morbidity

The two most prevalent neurodegenerative diseases are AD and PD. Epidemiologists, estimate that up to 4.5 million Americans suffer from AD, and 1.2 million from PD. This represents roughly 2.5% of the entire population in the United States. This estimate is likely valid for most, if not all, countries of the world as epidemiological studies have found roughly comparable incidence and prevalence rates of AD and PD around the globe. Nevertheless, some geographic and temporal clusters of neurodegenerative conditions have been described. Two such examples include the marked increase in cases of parkinsonism in connection to the influenza pandemic of 1918 (Casals et al., 1998), and the high incidence of PD-ALS-dementia complex confined to the Chamorro Indians who live on the Western Pacific Island of Guam (Chen and Chase, 1986). These clusters, while quite enlightening, must be regarded as the exceptions rather than the rules. The most consistent risk

factor for developing a neurodegenerative disorder, especially in regards to AD and PD, is increasing age (Tanner, 1992) and this fact may have far-reaching implications for the generations to come. As previously noted (Przedborski et al., 2003), over the past century, the growth rate of the population ages 65 and above in industrialized countries has far exceeded that of the population as a whole. Therefore, it can be anticipated that, over the next generations, the proportion of elderly citizens will double. Consequently, unless effective preventive strategies are soon found, the number of persons suffering from a neurodegenerative disorder will rise dramatically and the epidemiological numbers provided above may have to be amended to higher percentages.

It is also important to emphasize the fact that nearly all neurodegenerative disorders shorten the life expectancy of affected patients even if medications which alleviate the symptoms are available. This is well illustrated in the case of PD in which symptoms worsen over time. As discussed elsewhere (Dauer and Przedborski, 2003), before the introduction of the potent symptomatic treatment levodopa, the mortality rate among PD patients was three times that of the normal age-matched subjects. Unexpectedly, population-based surveys suggest that PD patients continue to display a decreased longevity compared to the general population despite the fact that motor problems can be controlled by levodopa (Levy et al., 2002; Morgante et al., 2000; Hely et al., 1989). Yet, only a few neurodegenerative disorders are fatal *per se*. Indeed, only those diseases which affect neurological structures that are implicated in controlling or driving vital physiological functions, such as respiration or circulation, are truly lethal. Amongst these is found ALS, where the losses of lower motor neurons innervating the intercostal and diaphragm muscles lead to fatal respiratory paralysis. In Friedreich ataxia, the association of neurodegeneration with heart disease (Harding, 1981) can also be a cause of death, although, in this case, death is not due to any neurodegenerative event, but instead to cardiodegenerative problems such as congestive heart failure. In most other neurodegenerative disorders, death is attributed neither to the damage of the nervous system nor to any associated extra-nervous system degeneration, but rather to medical problems including fatal falling, aspiration pneumonia, pressure skin ulcers, malnutrition, and dehydration, whose occurrence is favored by immobility, impaired balance, and cognitive decline. The leading causes of death in our industrial societies include cancers and cardiovascular problems. As a result it is worth mentioning that medical co-morbidity such as atrial fibrillation and cancer double the chances of death in nursing homes of demented patients (Van Dijk et al., 1996). Cardiovascular problems, such as high blood pressure, have also been suggested to stimulate the dementing process (Doraiswamy et al., 2002). Thus, medical co-morbidities appear to aggravate the long-term prognosis of patients inflicted with a neurodegenerative disease. However, whether or not patients suffering from a neurodegenerative disease are at greater risk for cancer, stroke, or heart attack, remains to be demonstrated.

17.3. Classification

The estimated number of different neurodegenerative diseases is a few hundred. Among these, many appear to overlap with one another clinically and pathologically. Classification of neurodegenerative diseases, while useful, is quite a complicated task. In neurodegenerative diseases, it is typical that several areas of the brain are affected. Yet, the degrees in which these different brain areas are damaged often vary from one case to another, thus giving rise to different phenotypes. For example, in a disease such as multisystem atrophy where typically parkinsonism is a prominent feature, it may be accompanied with either severe ataxia, autonomic failure, or both, depending on whether, in addition to the basal ganglia, the cerebellum and the intermediolateral column of the thoracic spinal cord also degenerate (Wenning et al., 2004). Even in the case of a defined genetic defect, a similar mutation may also produce varied phenotypes. For instance, in familial parkinsonism linked to mutations in the leucine-rich repeat kinase-2 (LRRK2) gene, a striking pleomorphic pathology has been reported with some members of the affected family, developing a motor neuron disease superimposed to dementia and/or parkinsonism (Zimprich et al., 2004). Despite these difficulties, it remains that the most popular categorization of neurodegenerative disorders is based on either the main clinical feature or the location of the predominant lesion, or often on a combination of the two. This proposed classification has been discussed previously (Przedborski et al., 2003) and will be repeated here for the sake of completeness of this chapter. We have proposed that neurodegenerative disorders may be grouped into diseases of the main anatomical division of the central nervous system: cerebral cortex, basal ganglia, brainstem/cerebellum, and spinal cord. Within each anatomical group, diseases may be sub-grouped based on their main clinical features.

Based on this clinico-anatomical classification, diseases of the cerebral cortex may be divided into cortical diseases associated with dementia (e.g., AD) and without dementia. In theory, circumscribed degeneration of the cerebral cortex can occur in absence of dementia as reported in some cases of progressive primary aphasia (Kirshner et al., 1987). However, because the cerebral cortex is so heavily involved in cognition, neurodegeneration, over time, often spreads beyond the initial locus of pathology, and the majority of these patients end-up with dementia (Le Rhun et al., 2005). It is thus not surprising to find that neurodegenerative diseases of the cerebral cortex are usually equated to dementia. While AD in this group of diseases is by far the most frequent (Sulkava et al., 1983), about 50 other and less prominent dementing cortical diseases can be found (Tomlinson, 1977).

Diseases of the basal ganglia are essentially characterized by abnormal motor activity. Based on the type of motor problem, diseases of the basal ganglia can be classified into hypokinetic or hyperkinetic groups. Hypokinetic basal ganglia disorders include PD, in which the amplitude and velocity of voluntary movements are diminished or, in extreme cases, non-existent.

Aside from PD, parkinsonism—which refers to an association of at least two of the following clinical signs: resting tremor, slowness of movements, stiffness, and postural instability—is also found in a variety of other diseases of the basal ganglia (Dauer and Przedborski, 2003). In some, there is only parkinsonism (e.g., striatonigral degeneration) but in others, often called parkinson-plus syndromes, there is parkinsonism plus signs of cerebellar ataxia (e.g., olivopontocerebellar atrophy), orthostatic hypotension (e.g., Shy-Drager syndrome) or paralysis of vertical eye movements (e.g., progressive supranuclear palsy). Because early on, Parkinsonism may be the only clinical expression of parkinson-plus syndromes, it is difficult to diagnose accurately before the patient reaches a more advanced stage of the disease. This problem is particularly well depicted by the fact that more than 77% of patients with parkinsonism are diagnosed in life as having PD (Stacy and Jankovic, 1992), but as much as a quarter of the diagnosed patients are found at autopsy to have lesions incompatible with PD (Hughes et al., 1992). Of note, it is customary to classify the stiff-person syndrome among the hypokinetic diseases. However, available evidence would argue that the stiff-person syndrome while being a hypokinetic condition is an autoimmune disease involving the nervous system and not a neurodegenerative disease.

Found at the other end of the spectrum are the hyperkinetic basal ganglia disorders, which are represented by HD and essential tremor. In these two conditions, excessive abnormal movements such as chorea or tremor are superimposed onto and interfere with normal voluntary movements. Although hyperkinetic basal ganglia disorders are probably as diverse as hypokinetic basal ganglia disorders, their specific disease markers such as gene mutations, which exist for several of the hyperkinetic syndromes create more accurate, less problematic, classifications.

All neurodegenerative diseases of the cerebellum and its connections are clinically associated with ataxia, meaning that the main criteria of classification will rely less on the clinical presentation than on the loci of pathology. Some diseases of the cerebellum and connections can easily be grouped into three main neuropathological types: cerebellar cortical atrophy (lesion confined to the Purkinje cells and the inferior olives); pontocerebellar atrophy (lesion affecting several cerebellar and brain structures); and Friedreich ataxia (lesion affecting the posterior column of the spinal cord, peripheral nerves, and the heart). However, several other diseases of the cerebellum and its connections fall somewhere in between these three well-delineated categories: dentorubral degeneration, in which the most conspicuous lesions are in the dentate and red nuclei, and Machado-Joseph disease, in which degeneration involves the lower and upper motor neurons, substantia nigra, and the dentate system.

Among the neurodegenerative diseases predominantly affecting the spinal cord are ALS and spinal muscular atrophy, in which the most severe lesions are found in the anterior part of the spinal cord, and the already cited Friedreich ataxia,

in which the most severe lesions are found in the posterior part of the spinal cord. Finally, there is one group of neurological diseases which are often, but not always, considered neurodegenerative because of their chronic course and unknown etiopathogenesis, unlike those described above, these show no apparent structural abnormalities. These include torsion dystonia, Tourette syndrome, essential tremor, and schizophrenia. Structural abnormalities are referred to here as a loss of neuronal cell bodies, but it is unknown whether or not structural damage restricted to synaptic connections occurs in torsion dystonia or schizophrenia, which could account for the disease phenotype. Moreover, in all of these singular neurodegenerative disorders, various brain imaging studies and electrophysiological investigations have revealed significant functional abnormalities.

The above discussion was aimed at stressing some of the obtrusive shortcomings of the current classification of neurodegenerative diseases. To circumvent these problems researchers have tried over the recent years to move away from the conventional clinical/neuropathological system of classification and instead invest in a molecular-based classification system. Based on this novel approach, some neurodegenerative diseases, which used to belong to very distinct categories, are now brought together because of a common molecular alteration. For example, HD, spinal-cerebellar atrophy, and myotonic dystrophy now fall under the category of the trinucleotide repeat disorders (Cummings and Zoghbi, 2000); Creutzfeldt-Jakob disease, Gerstmann-Straussler-Scheinker syndrome, and fetal familial insomnia fall under the category of the prion diseases (Prusiner, 1998); PD, progressive supranuclear palsy, and diffuse Lewy body dementia fall under the category of the synucleinopathies (Galvin et al., 2001); and AD, corticobasal degeneration, fronto-temporal dementia with parkinsonism linked to chromosome-17, and Pick disease fall under the category of tauopathies (Goedert and Spillantini, 2001). Although the jury is still out on whether or not this new type of classification will alleviate the problems previously encountered, we strongly believe that a recasting of the conventional neuropathological-based classification to a molecular-based classification holds the promise of a more practical and less ambiguous standing for neurodegeneration from a clinical and therapeutic point-of-view.

17.4. Etiology of Neurodegenerative Diseases

The word *etiology* refers to the initiating factor of a disease. In some cases a given clinical entity is linked to a single etiological factor such as in HD. Interestingly, however, several others can be caused by various and quite distinct factors. PD for example can be caused by overexpression of the small synaptic protein alpha-synuclein (Singleton et al., 2003), loss of parkin E3-ubiquitin ligase activity (Shimura et al., 2000), or by an increase in kinase activity of LRRK2 (West et al., 2005). These observations raise an important issue that plagues the field of neurodegeneration which is whether prominent disorders such as PD or AD are indeed diseases

or rather syndromes, i.e. very different diseases are lumped together under a same name because they merely share the same clinical expression.

Regardless of this problem, it should be known that the causes of neurodegenerative diseases or syndromes are in most instances unknown. Even in some rare cases when the etiology has been identified, the mechanism by which the etiological factor leads to neuronal death remains, at best, speculative. For example, while the etiology of HD was identified more than 20 years ago (The Huntington's Disease Collaborative Research Group, 1993), we still do not know with certainty how mutant huntingtin kills striatal neurons. The same circumstances are also true for superoxide dismutase-1 whose mutations are linked to a familial form of ALS (Rosen et al., 1993).

Among the neurodegenerative diseases, only a few arise as a familial condition, supporting a genetic basis. Within the affected members of a family, these genetic diseases can run as an autosomal dominant condition, which is the case for HD and dentatorubral-pallidoluysian atrophy. Less frequently, the disease can run as an autosomal recessive (e.g., familial spastic paraparesis), an X-linked (e.g., spinal and bulbar muscular atrophy), or even a maternally inherited trait (e.g., mitochondrial Leber optic neuropathy). In addition to these genetic-neurodegenerative diseases, others, while primarily sporadic, can also show a small contingent of patients in whom the illness is inherited. This is the case for PD, AD, and ALS, where less than 10% of all cases are generally familial.

For those in whom the disease is truly sporadic, which is the vast majority of patients, it appears that any genetic contribution to the neurodegenerative process would be minimal (Tanner et al., 1999). In these cases, toxic environmental factors may be the prime suspects in initiating neurodegenerative processes. Relevant to this idea is the observation that some neurodegenerative conditions, as mentioned above, might arise in geographic or temporal clusters. For instance, in the case of the PD-ALS-dementia complex of Guam which was introduced previously, it is believed that the pathology is caused by a toxic compound contained in the *Cycas circinalis*, an indigenous plant commonly ingested as food or medicine by the Chamorros Indians (Kurtland, 1988). Intoxication with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, a by-product of the synthesis of a meperidine compound, is also known to produce a severe and irreversible parkinsonian syndrome, which is almost identical to PD (Przedborski and Vila, 2001). Several large-scale epidemiological studies have failed, however, to link in a definitive manner the environmental factors to diseases such as PD (Tanner, 1989). Furthermore, most of the toxic exposures known to cause neurological problems occur within a specific geographic, social, or professional context and in absence of any significant association with an increased incidence of PD, AD, or other prominent neurodegenerative diseases. Collectively, the aforementioned findings argue that sporadic cases are neither clearly genetic nor clearly environmental. This does not exclude the possibility

that neurodegenerative disorders can result from a combination of both. Along this line, the demonstration of a non-syndromic familial deafness linked to a mitochondrial point mutation (Prezant et al., 1993) provides compelling support for this view. In this study, family members who harbor the mitochondrial mutation develop a hearing impairment only upon exposure to the antibiotic aminoglycoside, thus illustrating the significant pathogenic interactions between genetics and environment.

17.5. Pathogenesis of Neurodegenerative Diseases

Compared to *etiology*, *pathogenesis* does not refer to the initiation of the disease process, but rather to the cascade of cellular and molecular mechanisms set into motion by the etiological factor(s) which ultimately leads to the demise of the affected neurons. As mentioned above, only very small group of so-called neurodegenerative conditions comprise a set of diseases with no apparent neuropathological changes. In all others, overt neuropathology, mainly in the form of a focal loss of neurons with gliosis, is discernable. Residual neurons may exhibit varying morphologies ranging from an almost normal appearance to a severe distortion with a combination of abnormal features such as process attrition, shape and size alterations of the cell body and nucleus, organelle fragmentation, dispersion of Nissl bodies, cytoplasmic vacuolization, and chromatin condensation. In several neurodegenerative disorders, spared neurons can also present with various types of intracellular proteinacious inclusions, which, in the absence of any definite known pathogenic role, are quite useful in differentiating neurodegenerative disorders. As for the glial response, it is comprised of innate resident immune cells including astrocytes and microglia. To a lesser extent, adaptive immune cells such as T-lymphocytes can also be found in the diseased areas of the brain.

All neurodegenerative disorders associated with cell death have in common the fact that specific subpopulations of neurons degenerate at the level of specific structures of the nervous system. This means that autopsy areas of the brain that are damaged can be surrounded by healthy tissues and that within the affected regions, degenerating and healthy neurons are intermingled. In some neurodegenerative diseases, such as olivopontocerebellar atrophy, multiple brain structures within the nervous system are affected. In these so-called *system neurodegenerative diseases*, the spatial pattern of the lesions often becomes better defined as the disease progresses (Przedborski et al., 2003). In regards to the spatial pattern of the lesions it is essentially unrelated to the distribution of blood vessels. Conversely, as emphasized by Oppenheimer and Esiri (1997) the different lesions appear, at least in some cases, functionally and anatomically interconnected. Such a linked degeneration is observed in ALS, where both the corticospinal track and spinal cord lower

motor neurons are affected, or in progressive supranuclear palsy, where both the globus pallidus and the subthalamic nucleus are lesioned. Although such trans-neuronal degeneration is a well-recognized phenomenon (Saper et al., 1987), very little is known about its molecular basis except for the fact that this trans-synaptic demise occurs by programmed cell death (DeGiorgio et al., 1998; Ginsberg and Martin, 2002). Trans-neuronal degeneration is unlikely to account for all of the combinations of lesions that are found in system neurodegenerative diseases. In Friedreich ataxia, there is degeneration of the spinocerebellar tracts and the dentate nuclei, but not of the Purkinje cells, which would have been the link between these two lesions. It is thus more probable that etiological factors are ubiquitous, and that the pathological threshold is attained by specific structures of the nervous system at different times. Perhaps, in some neurodegenerative diseases, some areas of the nervous system may never reach this threshold and will thus remain unaffected throughout the span of the disease. Also, not in all neurodegenerative disorders are large numbers of areas of the nervous system at risk. In some specific neurodegenerative diseases, the lesions appear restricted to one or only a few brain regions. This is particularly well illustrated in spinal muscular atrophy, in which the degenerative process is limited to a loss of lower motor neurons, or in ALS, which is characterized by damage to the upper and lower motor neurons which may represent the sole neuropathological change. Nevertheless, almost all neurodegenerative disorders, which initially appeared *monosystemic*, will eventually become *multisystemic* over the progression of the degenerative process. In ALS for example it is typical to observe overt neuropathological changes mainly at the level of the spinal cord and motor cortex in patients who died after the short course of the disease, for unrelated causes (i.e. car accident or heart attack). However, in ALS patients with a more protracted course, degenerative changes can now also be detected in the substantia nigra (Sasaki et al., 1992) and the oculomotor and trochlear nuclei (Hayashi et al., 1991). Recognition of this temporal spreading of the neurodegenerative process has lead some neuropathologists (Braak et al., 2003) to propose that the neurodegenerative process starts on a specific circumscribed area of the nervous system where it begins a domino-effect: the initial affected area is responsible for the disease occurring in the next region, whereby propagating the degenerative process. Although quite appealing, this model is speculative and would only be true if the different regions affected in the neurodegenerative conditions were anatomic neighbors which is often not the case.

In most, if not all, neurodegenerative disorders the locations of the principal lesions have been well established. However, it often remains difficult to determine the extent of degeneration affecting more than one group of neurons and, consequently, to define the exact neuropathological topography of certain diseases. This problem stems from at least three issues. First, lesions are often missed through incomplete examination of the brain and spinal cord. Second, quantitative morphology in

post-mortem samples seldom use the rigorous counting methods necessary to generate reliable neuron numbers (Saper, 1996). The third issue pertains to sick neurons, which will not necessarily die. These compromised neurons often lose their phenotypic markers which are used for identification purposes in order to count them (Clarke and Oppenheim, 1995). Accordingly, the use of phenotypic markers in pathological conditions may lead to erroneous conclusions about the status of a given group of neurons. For these reasons, reported estimations regarding the distribution and magnitude of neuronal loss in neurodegenerative disorders, perhaps with a few exceptions, may have to be taken with caution.

17.6. Onset and Progression of the Disease

As indicated above, prominent neurodegenerative disorders are sporadic and with the absence of pre-symptomatic markers for virtually all of them, patients are seeking medical attention only when the first symptoms of the diseases emerge. Because there is significant cellular redundancy in neuronal pathways, the onset of symptoms does not equate with the onset of the disease. Instead, the beginning of symptoms merely corresponds to a neurodegenerative stage at which the number of residual neurons in a given pathway drops below the number required to maintain its endowed function. It is thus clear that the onset of the disease occurs at some preceding time, which, depending on how fast the neurodegenerative process evolves, can range from a few months to several years. Our ability to determine the actual onset of the disease is at this point unfortunately undermined by the lack of pre-symptomatic markers and the little knowledge about the true kinetics of cell demise.

Occasionally, there is a sudden worsening of a patient's condition. Although a sudden acceleration of the neurodegenerative process cannot be excluded, especially under the effect of intercurrent deleterious factors such as infection, it is more probable that the rate of neuronal death remains about the same throughout the natural course of the disease. However, the relationship between the clinical expression of a disease and the number of residual neurons does not have to be either linear or even constant. For instance, a patient may clinically remain unchanged during a prolonged period of time despite a loss of many cells and then abruptly their condition may deteriorate as the number of neurons drop below a functional threshold. Another important aspect is that virtually all neurodegenerative disorders progress slowly over time, often taking several years to reach end-stage. It must be remembered that neuronal degeneration corresponds to an asynchronous death (Pittman et al., 1999) in that cells within a population die at very different times. The correlate of this fact is that at any given time, only a small number of cells are actually dying, and among these, they are at various stages along the cell death pathway. However, standard clinical, radiological, and biochemical measurements, which are critical to assessing the

disease, generate information about the entire population of cells. Therefore, the rate of change in any, of the usual clinical parameters reflects the decay of the entire population of affected cells and provides very little, if any, insight into the pace at which the death of an individual cell occurs. Still, if one looks at the large body of *in vitro* data, it appears that, once a cell gets sick, the entire process of death proceeds rapidly. Given these facts, it may be possible that the protracted clinical progression is the reflection of only a small number of neurons dying at any given time from a rapid demise.

17.7. Cell-Autonomous of the Degenerative Process

As indicated above, neurodegeneration refers to pathology of neurons. It is thus not surprising to find from an examination of the literature that all theories about neurodegeneration pathogenesis revolves around neurons. This rather *neuronocentric* view is increasingly at odds, however, with the current concept of neurodegeneration pathogenesis. As stressed above, in most prominent familial neurodegenerative diseases, the mutant proteins are ubiquitously expressed. This is the case, for example, with mutant α -synuclein in familial PD and of mutant SOD1 in ALS. While the underlying gene mutations are unquestionably pathogenic, ALS-linked SOD1 mutations expressed selectively in astrocytes (Gong et al., 2000) or in neurons (Pramatarova et al., 2001; Lino et al., 2002) fail to provoke the death of motor neurons in transgenic mice. Conversely, the expression of ALS-linked SOD1 mutations in all cells do cause an adult-onset paralytic phenotype in both transgenic mice and rats (Gurney et al., 1994; Nagai et al., 2001). Further support to the idea that many different cell types collaborate to achieve the demise of neurons in neurodegenerative diseases comes from the work of Clement et al. (2003). In the study, the authors produced chimeric animals made of mixtures of normal and SOD1 mutant-expressing cells. They found that motor neurons that chronically expressed mutant SOD1 did not degenerate if they were surrounded by a sufficient number of normal non-neuronal cells. In addition, normal motor neurons surrounded by mutant-expressing non-neuronal cells were shown to acquire intraneuronal ubiquitinated deposits consistent with the concept that mutant-expressing cells could transfer the diseases phenotype to normal neighboring cells. These data provide a compelling argument in that death of neurons in neurodegenerative diseases such as ALS may not be as cell-autonomous as previously thought. Accordingly, the cellular environment surrounding neurons may play a critical role in determining the fate of specific neurons within these types of diseases of the nervous system. Among the prime candidates that mediate this non-cell autonomous mechanism of neurodegeneration are glial cells. Along this line, neuroinflammation has indeed emerged over the past decade as a key contributor to neurodegeneration in

diseases such as AD, PD and ALS (Wyss-Coray and Mucke, 2002; Przedborski and Goldman, 2004; McGeer and McGeer, 2002). Based on both epidemiological and pre-clinical studies in animal models of human diseases (Chen et al., 2003; Wyss-Coray and Mucke, 2002; Przedborski and Goldman, 2004; McGeer and McGeer, 2002), it is now proposed that neuroinflammation could stimulate neurodegeneration.

Summary

Neurodegenerative diseases represent a heterogeneous group of disorders affecting the nervous system. In most instances, they affect adults, their causes are unknown, and progression is relentless. Some are genetic, but most are sporadic. They involve all parts of the nervous system, although the cerebral cortex and the basal ganglia are the most frequent loci of pathology. The historical classification of neurodegenerative diseases, based on clinical and pathological characteristics, is imperfect. New classifications are rather based on molecular determinants. Contrary to common belief, it is now recognized that neurodegenerative disorders are multisystemic, even if specific neuronal pathways are more affected than others. The death of specific types of neurons in neurodegenerative diseases is provoked, not by a single pathogenic factor, but rather by a cascade of multiple deleterious molecular and cellular events.

Acknowledgments. The author wishes to thank Ms. Julia Jeon for assistance in preparing this manuscript. This study is supported by Muscular Dystrophy Association/Wings-over-Wall Street, NIH/NINDS Grants NS38586, NS42269, NS38370, and NS11766–27A2, NIH/AG 021191, the US Department of Defense Grant (DAMD 17–99–1–9474 and DAMD 17–03–1), the Loewenstein Foundation, the Smart Foundation, the Parkinson's Disease Foundation.

Review Questions/Problems

- 1. Define neurodegeneration.**
- 2. What are the three broad categories of diseases of the nervous system?**
- 3. Provide examples of diseases from the three categories.**
- 4. What is expected to occur with the prevalence of neurodegenerative diseases in the forthcoming generations and why?**
- 5. What is the effect of neurodegeneration on the life expectancy and for what reason(s) do patients with neurodegenerative disease typically die?**
- 6. What is the common method used in classifying neurodegenerative diseases and what are the difficulties inherent with this type of classification?**

- 7. Describe the different forms of genetic contributions among the neurodegenerative diseases.**
- 8. What does multisystemic neurodegeneration refer to?**
- 9. Why are neurodegenerative diseases progressive and what does it mean at the level of the whole population of affected cells and a single affected cell?**
- 10. Define the notion of non-cell autonomous neurodegeneration and provide an example.**
- 11. What are the two most prevalent neurodegenerative diseases?**
 - a. Alzheimer's disease and stroke
 - b. Parkinson's disease and brain tumor
 - c. Alzheimer's disease and Parkinson's disease
 - d. Huntington's disease and amyotrophic lateral sclerosis
 - e. Mitochondrial encephalopathy and multiple sclerosis
- 12. What are typical neurodegenerative diseases without overt neuropathology?**
 - a. Creutzfeldt-Jakob disease
 - b. Schizophrenia
 - c. Essential tremor
 - d. Torsion dystonia
 - e. All but a
- 13. What is the correct statement about the neuropathology of neurodegenerative diseases?**
 - a. Neuropathologic changes in neurodegenerative diseases are always detectable in at least one region of the nervous system.
 - b. Residual neurons look sick or normal.
 - c. In addition to the loss of neurons, there is always some gliosis and protein aggregates.
 - d. If different regions of the brain are affected, the type of neurons degenerating remains identical.
 - e. The multisystemic nature of a neurodegenerative process is explained by a trans-synaptic phenomenon.
- 14. What is the correct statement about the etiology of neurodegenerative diseases?**
 - a. The etiology of most neurodegenerative diseases is unknown.
 - b. Most neurodegenerative diseases are genetic.
 - c. Neurodegenerative diseases are only linked to nuclear gene defects.
 - d. Environmental toxic factors have never been implicated in the occurrence of neurodegenerative diseases.
 - e. Genetic/environmental interactions are unknown causes of neurodegeneration.
- 15. Which of the following statements is true about the pathogenesis?**
 - a. The death of neurons is caused by a unique pathogenic mechanism triggered by an etiologic factor.
 - b. Neurodegenerative disorders never become multisystemic upon progression of the disease.
 - c. It is established that the neurodegenerative process starts in one area of the nervous system and then spreads to others by a domino effect.
 - d. Before dying, compromised neurons never lose their functions and phenotypic markers.
 - e. The distribution and magnitude of neuronal loss in neurodegenerative disorders is often difficult to establish with certainty.
- 16. Which of the following statements are most correct?**
 - a. Onset of symptoms reflects the onset of the disease.
 - b. The prominent symptoms often reveal the main site of neuropathology.
 - c. Intercurrent infection can permanently exacerbate the symptoms.
 - d. Neurodegenerative diseases differ from non-degenerative diseases because the latter never progress in a step-wise manner.
 - e. b and c
- 17. Which of the following statements are always correct?**
 - a. Neurodegenerative diseases can involve either the central or the peripheral nervous systems, or both.
 - b. A familial occurrence of a neurodegenerative disease is the signature of its genetic origin.
 - c. Cardiovascular problems exacerbate the cognitive decline in patients with dementia and vice-versa.
 - d. Neurodegenerative diseases are associated with a shortened life-span because they eventually impair respiratory or cardiovascular functions.
 - e. When available, symptomatic agents normalize life-span in patients suffering from neurodegenerative diseases.
- 18. The transmissibility of a neurodegenerative phenotype can be?**
 - a. Autosomal dominant
 - b. Autosomal recessive
 - c. X-linked
 - d. Mitochondrial
 - e. All of the above
- 19. Regarding the classification of neurodegenerative disorders which statement is not correct?**
 - a. The clinico-anatomic classification is quite popular, but is fraught with many shortcomings.
 - b. The molecular classification groups together neurodegenerative diseases of very different clinical expression.
 - c. A parkinsonism can be observed in patients suffering from a wide variety of disorders including Parkinson's disease.
 - d. Members of a same family carrying an identical mutation always exhibit the same clinical and neuropathological phenotype.
 - e. A similar clinical phenotype can be caused by distinct etiologic factors.

20. The concept of non-cell autonomy in neurodegeneration implies.

- A disease phenotype can be transmitted from a mutant cell to a wild-type cell.
- The whole disease process does not rely solely on pathogenic events taking place in the degenerating cells.
- The fate of neurons destined to die is at least in part, determined by other cells such as neighboring glia.
- This concept applies to infectious diseases but not to neurodegenerative disorders.
- All but d

Multiple Sclerosis and Other Demyelinating Diseases

Samantha S. Soldan, Gregory F. Wu, Clyde E. Markowitz, and Dennis L. Kolson

Keywords Multiple sclerosis; experimental allergic encephalomyelitis; central nervous system; virus; cerebrospinal fluid; T-cell receptor; acute disseminated encephalomyelitis; lymphocyte; immune system

18.1. Introduction

Multiple sclerosis (MS) is the most common idiopathic demyelinating disease of the central nervous system (CNS). Although partially effective treatments are now available, MS represents a major target for research into the development of disease-modifying therapies that specifically focus on the neuroimmune pathways of myelin and tissue damage that currently are incompletely understood. Multiple sclerosis is considered to be an example of development of autoimmunity to self-antigens within the CNS through multiple initiating events that include infections and other environmental factors. The direct or indirect induction of immune responses against CNS antigens includes chemotaxis of T cells, B cells, and monocytes, and production of immunoglobulin responses, each of which can act as an effector of myelin damage that occurs in distinct histological patterns. Because a specific cause for MS has not been identified, much MS research has focused on CNS immune responses triggered by unidentified insults that in turn trigger inflammation-mediated cascades of myelin and cellular damage that are likely relevant to other neurodegenerative diseases. This chapter discusses current the epidemiology, etiology, pathophysiology, animal models, virus models and recent advances in the neuroimmunology of MS from the perspective of the potential for development of newer therapies for MS and other inflammatory CNS diseases.

18.2. Clinical Features and Diagnosis of Multiple Sclerosis

Multiple sclerosis (MS) is a disease of unknown etiology that primarily affects the myelin membrane and/or the oligodendroglia (myelin-producing cells) within the central nervous

system (CNS). The clinical features are highly variable, but they consistently reflect dysfunction due to inflammation, local edema, and destruction of the “central myelin” of the brain, spinal cord, and/or optic nerves (reviewed in Miller, 1996). Symptoms generally present with gradually increasing severity (days to weeks), followed by gradual resolution (weeks), which may be complete or partial. The frequency of different types of symptoms in MS is difficult to accurately establish, in part due to their highly variable severity and duration (Matthews, 1998). The most common neurological symptoms are focal sensory disturbances including numbness/tingling sensations, dysesthesiae (sensation), paresthesiae (abnormal sensation), L’hermitte’s sign (sudden electric-like sensations radiating into the arms or legs while flexing one’s neck), and occasionally burning pain. Such sensory disturbances occur in up to 70–80% of individuals during the course of MS (Miller, 1996; Matthews, 1998). Motor manifestations attributable to corticospinal tract dysfunction occur in up to 60% of patients, and often involve the lower extremities. Motor symptoms generally include dyscoordination and weakness that is often described as “heaviness” of an extremity, which may present unilaterally or bilaterally, in the case of spinal cord involvement. Optic nerve involvement, manifested as optic neuritis (inflammation of the optic nerve associated with visual loss) presents as the initial symptom in about 20% of MS patients, but its prevalence during the course of MS is thought to be much higher (Matthews, 1998).

The clinical course of the disease (reviewed in Ebers, 1998) is also variable, with approximately 70–85% of patients starting with a relapsing remitting disease pattern in which remissions are associated with complete or nearly complete recovery (Coyle, 2000). The disease typically gradually progresses (over years) so that remission periods are shorter and neurological recovery is incomplete. In the chronic phase, neurological dysfunction increases without significant improvement. Approximately 15% of patients have primary progressive MS, most commonly expressed as a progressive myelopathy. Other clinical courses have been described including an acute form with rapid neurologic deterioration and sometimes death within a few months, a progressive form

FIGURE 18.1. MRI signal abnormalities in the brain and spinal cord in a 55-year-old woman with multiple sclerosis. (A) FLAIR (Fluid attenuated inversion recovery) image of axial brain image at the level of the lateral ventricles. Arrows point to hyperintense periventricular lesions demonstrating a characteristic MS demyelination pattern; (B) T2W image of sagittal view of the spinal cord of the same individual, demonstrating focal bright signal (arrow) representing demyelination in the cervical spinal cord.

without defined remissions and relapses, and a benign form with a few exacerbations associated with complete recovery. A subclinical form has also been described based upon autopsy findings in asymptomatic individuals. MS can be viewed as a disease with multiple phenotypic presentations that are superimposed over pathological components that range from pure inflammation to gliosis.

Diagnostic criteria intended originally for the purposes of classifying patients for research protocols are now considered standard criteria for clinicians making the diagnosis of MS. The original clinical criteria of Schumacher (Schumacher et al., 1965) (reviewed in Coyle, 2000), were expanded by Poser (Poser et al., 1983) to incorporate paraclinical tests (MRI, cerebrospinal fluid analysis, and evoked potential testing) to increase the certainty of the diagnosis. The MRI typically demonstrates multifocal areas of demyelination surrounding the brain ventricles and within the spinal cord (Figure 18.1). The Poser criteria include the categories of clinically definite, laboratory-supported definite, probable, and possible multiple sclerosis. Previously, practicing clinicians generally attempted only to diagnose cases of definite MS (clinically definite or laboratory-supported definite) because of early recommendations for treatment of definite MS with the first FDA-approved immunomodulating medication, Interferon beta-1b/Betaseron. However, because recent clinical trials in individuals with single, clinically-apparent demyelinating events who did not meet Poser criteria for definite MS demonstrated that Interferon beta-1a (Avonex) greatly reduced the likelihood of development of definite MS over a 2-year period (Kinkel et al., 2006) clinicians have been advised to diagnose and treat patients with such isolated demyelinating events (Frohman et al., 2006b).

These diagnostic criteria, were again modified (Table 18.1) to include specific numbers and locations of MRI-defined lesions that can confirm the diagnosis of MS with a clinically monosymptomatic event or an insidious neurological progression suggestive of MS (McDonald et al., 2001; Polman et al., 2005). Included in Table 18.1 are the Poser criteria (Poser et al., 1983), McDonald criteria (McDonald et al., 2001) and the revised McDonald criteria (Polman et al., 2005). By the Poser criteria (Table 18.1, top two clinical presentations) “definite” multiple sclerosis requires objective evidence of central nervous system (CNS) dysfunction in ≥ 2 sites of involvement, predominantly in the white matter, relapsing-remitting or chronic progressive (>6 months) in patients between the ages of 10 to 50 years at onset of symptoms. Importantly, there must be no better explanation of the symptoms. These “attacks” may be motor, sensory, visual, or coordination deficits and must last more than 24 h (typically days to weeks). They may be subjective and amnesic (i.e. recalled historically by the patient) or demonstrable by a physician, and separate attacks must be separated in time by at least 30 days of significant improvement to be classified as distinct attacks. In addition, if a physician can demonstrate objective dysfunction in two anatomically separate regions of the CNS, criteria are met for clinically definite multiple sclerosis, assuming no better explanations of the symptoms.

18.3. Epidemiology and Etiology of MS

MS is the most common inflammatory disease of the CNS, affecting an estimated 2,500,000 people worldwide and 350,000 in the United States alone (Johnson, 1994) (Kantarci

TABLE 18.1. Diagnostic criteria for multiple sclerosis (Polman et al., 2005).

Clinical presentation	Additional data needed for MS diagnosis
Two or more attacks ^a ; objective clinical evidence of two or more lesions	None ^b
Two or more attacks ^a ; objective clinical evidence of one lesion	Dissemination in space, demonstrated by: MRI ^c <i>or</i> Two or more MRI-detected lesions consistent with MS plus positive CSF ^d <i>or</i> Await further clinical attack ^a implicating a different site
One attack ^a ; objective clinical evidence of two or more lesions	Dissemination in time, demonstrated by: MRI ^c <i>or</i> Second clinical attack ^a
One attack ^a ; objective clinical evidence of one lesion (monosymptomatic presentation; clinically isolated syndrome)	Dissemination in space, demonstrated by MRI ^c <i>or</i> Two or more MRI-detected lesions consistent with MS plus positive CSF ^d <i>and</i> Dissemination in time, demonstrated by: MRI ^c <i>or</i> Second clinical attack ^a
Insidious neurological progression suggestive of MS	One year of disease progression (retrospectively or prospectively determined) <i>and</i> Two of the following: a. Positive brain MRI (nine T2 lesions or four or more T2 lesions with positive VEP) ^f b. Positive spinal cord MRI (two focal T2 lesions) c. Positive CSF ^d

Note: If criteria indicated are fulfilled and there is no better explanation for the clinical presentation, the diagnosis is MS; if suspicious, but the criteria are not completely met, the diagnosis is “possible MS”; if another diagnosis arises during the evaluation that better explains the entire clinical presentation, then the diagnosis is “not MS.”

^a An attack is defined as an episode of neurological disturbance for which causative lesions are likely to be inflammatory and demyelinating in nature. There should be subjective report (backed up by objective findings) or objective observation that the event lasts for at least 24 h.

^b No additional tests are required; however, if tests (MRI, CSF) are undertaken and are negative, extreme caution needs to be taken before making a diagnosis of MS. Alternative diagnoses must be considered. There must be no better explanation for the clinical picture and some objective evidence to support a diagnosis of MS.

^c MRI demonstration of space dissemination must fulfill the criteria derived from Barkhof and colleagues (Barkhof et al., 2003) and Tintore and coworkers (Tintore et al., 2003).

^d Positive CSF determined by oligoclonal bands detected by established methods (isoelectric focusing) different from any such bands in serum or by an increased IgG index.

^e MRI demonstration of time dissemination must fulfill criteria demonstrated in Table 1 in Polman et al. (2005).

^f Abnormal VEP of the type seen in MS.

and Wingerchuk, 2006). Approximately 1 in 1,000 North Americans will develop MS over their lifetime. While women are 1.5 to 2 times as likely as men to develop MS, males with MS are likely to have a worse prognosis, more rapid disease progression, and later age of disease onset (Coyle, 2000). This evidence of gender dependent differences in disease outcomes suggests that there are sex-specific factors in the phenotypic variability and etiology of MS (Kantarci and Weinshenker, 2005). The etiology of MS is unknown, and the heterogeneous pathology of this disease suggests that several factors might be involved in the spectrum of idiopathic inflammatory demyelinating diseases (IDDs) that are encompassed in the diagnosis of MS (Hafler, 2004). It is believed that genetic, environmental, and immunological factors contribute collectively to the natural history and epidemiology of this disorder (Kurtzke and Wallin, 2000).

18.3.1. Genetic Epidemiology

Epidemiological, familial, and molecular studies of MS have supported a strong influence of genetic background on dis-

ease susceptibility (reviewed in Kurtzke and Wallin, 2000). The worldwide distribution of MS is skewed, with areas of high prevalence in North America, Europe, New Zealand, and Australia and areas of lower prevalence in South America, Asia, and Africa. In general, the prevalence and incidence of MS follow a north-south gradient in both hemispheres with individuals of Northern European ancestry more likely to be affected (Compston, 1994; Ebers and Sadovnick, 1994; Sadovnick et al., 1998). Therefore, the north-south gradient observed in the New World may reflect the propensity for individuals from regions of Europe with a high incidence of MS to migrate to the northern regions of the United States and Canada, and of individuals from regions of Europe with a lower incidence of MS to migrate to southern regions of the United States and South America (Ebers and Sadovnick, 1994; Sadovnick et al., 1998). In support of this theory, several studies have demonstrated different prevalences of MS among genetically disparate populations residing in the same geographic region. In a 1994 survey of MS in Australia, the prevalence of MS was found to be 37.1/100,000 in New South Wales and 29.4/100,000 in South Australia (McLeod et al.,

1994). Strikingly, no Aborigines or Torres Strait Islanders with MS were identified in this study (McLeod et al., 1994). In addition, the prevalence of MS is higher in Hungarians of Caucasian descent (37/100,000) than in Hungarian gypsies (2/100,000) (Kalman et al., 1991). Similarly, the prevalence of MS among people of Japanese decent living on the Pacific Coast (6.7/100,000) is considerably lower than that of Caucasians living in California (30/100,000). Of interest, it has been demonstrated that people of Japanese ancestry living on the West Coast of the United States have a slightly higher prevalence of MS than those living in Japan (2/100,000) suggesting that environmental factors also have a significant impact on disease susceptibility (Detels et al., 1977).

Family and twin studies clearly support a genetic influence in the development of MS. It has been demonstrated that biological relatives of MS patients have a greater likelihood of developing MS than adoptees and that conversely, family members of adopted individuals with MS do not have an increased risk of developing the disease (Ebers et al., 1995). Among biological relatives, the lifetime risk of developing MS increases with closer biological relationships and approximately 20% of MS patients have an affected family member (Sadovnick, 1993). First-degree relatives, particularly sisters, of an individual with MS are 20–40 times more likely to develop MS and the risk of MS decreases rapidly with second- and third-degree relatives (Sadovnick et al., 1998; Sadovnick and Ebers, 1993; Ebers et al., 1995). In addition, the rate of MS concordance is eight times greater in monozygotic than dizygotic twins. However, the concordance among monozygotic twins is only 25–30%, suggesting that genetic background is not sufficient to cause the disease (Bobowick et al., 1978). Therefore, a combined influence of genetic background and the environment in the development of MS has been proposed.

Considerable effort has been made to assign MS susceptibility to classical models of inheritance. However, the inheritance of MS does not conveniently fit any of these models. The ability to attribute a particular inheritance pattern to MS may be confounded by the difficulty in diagnosing this unpredictable disease. Moreover, because the age of risk ranges from the late teens to the late 50s, an individual cannot be considered unaffected with certitude until they are past the age of high risk. Over the years, several genes associated with immune function have been tentatively associated with an increased risk of MS. A strong association between MS and the major histocompatibility complex (MHC) class II alleles DRB1*1501-DQB1*0602 has been demonstrated (Lincoln et al., 2005). The MHC class I allele A201 has been shown to have protective effects (Sospedra and Martin, 2005). In addition, recent studies have suggested that polymorphisms of the cytokine interferon- γ (IFN- γ) are associated with MS susceptibility in a gender dependent manner (Kantarci et al., 2005).

18.3.2. Environmental Epidemiology

The variation in disease incidence and prevalence according to geography (chiefly by distance from the equator), the influence of migration from low-to-high and high-to-low preva-

lence areas, and the observation of epidemics and clusters of MS all support an environmental influence on MS etiology (Kurtzke and Wallin, 2000). Migration studies based chiefly on Europeans who immigrated to South Africa, Israel, Australia, and Hawaii have also supported an infectious etiology of MS (Alter et al., 1978; Alter and Okihito, 1971; Kurtzke et al., 1970; Casetta and Granieri, 2000). In general, individuals who migrate from high risk to low risk areas after the age of 15 maintain their risk of MS. However, individuals who migrate from high risk to low risk areas before the age of 15 acquire a lower risk. These data suggest that an environmental factor must be encountered before the age of 15 in order to influence MS susceptibility. In addition, examples of MS epidemics have been described in the Faroe Islands, the Shetland-Orkney Islands, Iceland, Sardinia, Key West Florida, Mossyrock Washington, South Africa, and Mansfield Massachusetts (Kurtzke, 1995; Pugliatti et al., 2002). Albeit rare, these epidemics support an infectious etiology of MS.

A wide range of environmental factors including vitamin D, smoking, exposure to solar ultraviolet radiation, exposure to organic solvents, household pets, and dietary fatty acids have been associated with the risk of developing MS (Soilu-Hanninen et al., 2005; Schiffer et al., 2001; Neuberger et al., 2004; Hernan et al., 2005; Riise et al., 2002). In addition, infectious agents have been suspected in the etiology of MS for over a century (Johnson, 1994). Dr. Pierre Marie, a pupil of Dr. Jean Martin Charcot who first classified MS and named the disorder *sclerose en plaque*, was the first to suggest an infectious etiology for MS. Marie hypothesized that MS was triggered by an infection that led to changes in blood vessels ultimately resulting in an inflammatory interstitial reaction of glial cells. In addition, Marie believed that many organisms were involved in the pathogenesis of MS based on the anecdotal association of acute infectious diseases (including malaria, typhoid, and childhood exanthem) with the onset of disease.

An infectious etiology of MS is consistent with a number of epidemiological observations as well as the pathological characteristics of this disease (reviewed in Soldan and Jacobson, 2004). It has been speculated that the infectious component in the development of MS might be a virus. Data implicating a virus in the pathogenesis of MS include: (a) geographic association of disease susceptibility with evidence of MS clustering (Haahr et al., 1997); (b) evidence that migration to and from high risk areas influences the likelihood of developing MS (Alter et al., 1978; Weinshenker, 1996); (c) abnormal immune responses to a variety of viruses; (d) epidemiological evidence of childhood exposure to infectious agents and an increase in disease exacerbations with viral infection (Johnson, 1994; Weinshenker, 1996); and (e) analogy with animal models and human diseases in which viruses can cause diseases with long incubation periods, a relapsing remitting course, and demyelination. It has been hypothesized that infectious diseases could induce MS either through molecular mimicry (the activation of autoreactive cells via cross-reactivity between foreign and

self-antigens), bystander activation (activation of autoreactive cells through nonspecific inflammation), or a combination of the two.

Viruses have been implicated in a number of demyelinating diseases of the CNS in humans and other animals. The association of viruses in other demyelinating diseases further suggests a viral influence in the development of MS, by demonstrating that viruses are capable of inducing demyelination, and that they can persist for years in the CNS presenting chronic diseases long after acute infection. Viruses involved in demyelinating diseases of humans and animals include JC virus, measles virus, HTLV-I, canine distemper virus (CDV), murine coronavirus (JHM strain), Theiler's mouse encephalomyelitis virus (TMEV), and Visna virus (reviewed in Soldan and Jacobson, 2004). Over the years, several viruses have been associated with MS, and these associations are based primarily on elevated antibody titers or the isolation of a particular virus from MS material. However, none of these viruses have demonstrated a definitive cause-effect relationship with the disease. Elevated antibody titers to several infectious agents including influenza C, herpes simplex (HSV), human herpes virus-6 (HHV-6), measles, varicella-zoster (VZV), rubeola, vaccinia, Epstein-Barr virus (EBV), simian virus 5 (SV5), multiple sclerosis retrovirus (MSRV), and *Chlamydia pneumoniae* have been reported (reviewed in Soldan and Jacobson, 2004). Although most of these reported agents have been discounted from consideration in the pathogenesis of MS, a few remain viable candidates.

18.3.3. Immunological Influences

In addition to genetic and environmental influences, it is widely accepted that T cell-mediated immune responses are involved in the etiology of MS (reviewed in Frohman et al., 2006a). This is based on the association of MS with genes involved with the immune response, the immunopathology of the disease, the clinical response of MS patients to immunosuppressive and immunomodulatory treatments, and similarities with experimental immune-mediated demyelinating diseases in animals.

A number of immune abnormalities are frequently observed in MS patients and lend support to an immunologic component of the MS disease process. One of the hallmarks against unknown CNS antigens of MS is the intrathecal secretion of oligoclonal antibodies, also known as oligoclonal bands (OCB) as seen by immunofixation electrophoretic separation. OCB are found in the CNS tissue and CSF of greater than 90% of MS patients (when determined by isoelectric focusing electrophoresis) (Fortini et al., 2003) and are helpful in confirming the diagnosis of the disease. OCB are not specific to MS as they are also found in several other chronic inflammatory CNS conditions of either infectious (CNS Lyme disease, bacterial meningitis, human immunodeficiency virus/HIV infection, neurosyphilis) or autoimmune (CNS lupus erythematosus, neurosarcoidosis) origin. Although OCB are not directed against a single antigen,

antibody bands specific for viral, bacterial, and self-antigens have been described (Sindic et al., 1994; Sriram et al., 1999). Therefore, it is unclear whether or not the intrathecal synthesis of immunoglobulins observed in MS results from the presence of disease-related lymphocytes or cells that are passively recruited into the CNS after the pathogenically relevant cells crossed the blood brain barrier (BBB).

In addition to the presence of OCB, other immunological markers of disease activity have been described in MS. The overexpression of several proinflammatory cytokines, including tumor necrosis factor- α (TNF- α) and interferon- γ (IFN- γ) have been demonstrated in MS (Ubogu et al., 2006; Frohman et al., 2006b). Treatment of MS patients with IFN- γ resulted in a marked increase in exacerbations which supports the model of MS as an autoimmune disease mediated by T-helper-1 (TH-1) like T-cells. Furthermore, an increase in TNF- α expression has been found to precede relapses and inflammatory activity as measured by MRI, while the mRNA levels of inhibitory cytokines, such as interleukin-10 (IL-10) and transforming growth factor- β (TGF- β), declined (Rieckmann et al., 1995). Recently expression of ADAM-17, a disintegrin and metalloproteinase that is the major proteinase responsible for the cleavage of membrane-bound TNF, was found to be upregulated in MS lesions (Plumb et al., 2006). The overexpression of these cytokines may be involved in disease pathogenesis by causing the upregulation of MHC and adhesion molecule expression on endothelial and glial cells, activation of macrophages and recruitment of TH-1 cells, or by damaging oligodendrocytes and myelin sheaths directly (Selmaj and Raine, 1988). In addition, peripheral blood mononuclear cells (PBMCs) from MS patients have been demonstrated to have increased numbers of chemokine receptor 5 (CCR5) producing cells (Strunk et al., 2000). However, individuals who fail to express a functional CCR5 receptor (due to a common deletion mutation, CCR5 delta 32, carried by 1% of the Caucasian population) are no more likely to develop MS than those with normal CCR5 expression (Bennetts et al., 1997). Finally, soluble adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1) and E-selectin are elevated in MS sera while soluble vascular cell adhesion molecules VCAM-1 and E-selectin are increased in the CSF of MS patients (Dore-Duffy et al., 1995).

Additional support for MS as a disease with an autoimmune component is provided by the clinical improvement obtained with immunomodulatory and anti-inflammatory therapies (Galetta et al., 2002). Although treatment with corticosteroids does not attenuate the long-term course of MS, it is used effectively in the treatment of MS exacerbations. It has been demonstrated that the administration of high-dose steroids immediately stops blood-brain barrier leakage as visualized by gadolinium-enhanced magnetic resonance imaging (MRI) (Simon, 2000). A number of immunosuppressive and chemotherapeutic drugs including cyclophosphamide, and methotrexate have been used in the treatment of MS with variable success. Other immunomodulatory therapies recently used in MS including interferon- β (IFN- β), Copolymer-1 (COP-1)

and the humanized monoclonal antibody to the $\alpha 4$ -integrin of the VLA-4 adhesion molecule (Tysabri [Antegren or Natalizumab]) are reviewed in Chap. 11.

18.4. Pathophysiology of MS

18.4.1. Histology and Physiology of MS Lesions

The hallmark of MS is the white matter “plaque,” an area of demyelination usually around a blood vessel with perivenular cell infiltration and gliosis (Frohman et al., 2006a). Recent studies have shown that axonal injury is common in chronic plaques and is an important determinant of permanent loss of neurologic function and disability (Trapp et al., 1999). The analysis of biopsy specimens collected for differential diagnosis and autopsy cases from patients with MS with at least one lesion in the active stages of demyelination has demonstrated four histologically-defined patterns of demyelination, Patterns I-IV (Lucchinetti et al., 2000). All four patterns demonstrate macrophage and T-cell inflammation, although they vary in associated pathological findings. Patterns I and II share macrophage and T-cell-associated inflammation and are described as follows: Pattern I (“macrophage mediated,” macrophage- and T-cell associated demyelination, perhaps dominated by products of activated macrophages), Pattern II (“antibody mediated,” same infiltrates as I, but with prominent IgG and complement/C9neo deposition). These patterns are largely restricted to small veins and venules and are suggestive of T-cell initiated processes in which macrophages and/or antibodies are important effector functions. They are felt to be immunopathologically closest to EAE. Lesions in Patterns III and IV are not typically seen in EAE. Pattern III (“distal oligodendroglipathy”) and Pattern IV (“primary oligodendrocyte damage with secondary demyelination”) also demonstrate inflammatory macrophages and T-cells, but deposition of IgG and complement are absent. Pattern III shows degeneration of distal oligodendrocyte processes, loss of oligodendrocytes by apoptosis at the plaque border, and loss of MAG (myelin associated glycoprotein) expression with preservation of PLP (proteolipid protein), MBP (myelin basic protein) and CNPase (cyclic nucleotide phosphodiesterase) staining. This pattern might represent a T-cell-mediated small vessel vasculitis with secondary ischemic damage to the white matter. However, demyelination in Pattern III is distinct from that in I and II in not being centered around veins and venules. Pattern IV also demonstrates prominent oligodendrocyte degeneration without apoptosis, and demyelination may be induced by T-cell and macrophages on the background of metabolically impaired oligodendrocytes. This pattern might be restricted to individuals with the primary progressive form of MS. Remarkably this study found no evidence for intra-individual variability in the plaque morphology: plaques within an individual patient showed similar morphology.

The net physiological consequences of immune-mediated myelin disruption are partial or total conduction block, slowing of conduction, and ephaptic cross-activation due to disruption of salutatory conduction mediated by the nodes of

Ranvier in myelinated fibers (reviewed in McDonald, 1998). Demyelinated fibers are incapable of transmitting impulse trains at physiological frequencies, and such a defect likely contributes to the sensory and motor disturbances seen in MS. Such conduction delays are often detected in the optic nerves through visual evoked potential (VEP) testing (McDonald, 1976). An interesting form of intermittent conduction block that is characteristic of multiple sclerosis is that precipitated by changes in temperature. Heat-induced visual acuity loss (Uhthoff’s phenomenon), weakness, and fatigue have all been attributed to heat-induced conduction disturbances, and such symptoms often resolve through decreasing body temperature (Guthrie and Nelson, 1995).

18.4.2. Immunopathogenesis of Myelin Damage in MS

Although the etiology of MS is unknown, there is considerable consensus on the role of immune-mediated mechanisms in disease pathogenesis. The following evidence has led to the concept that helper CD4+ T cells coordinate specific autoimmune responses to one or more candidate autoantigens of central myelin: (1) in the white matter lesions, perivenular infiltrates mainly contain lymphomononuclear cells, including CD4+ and CD8+ T cells, macrophages, and B cells; (2) the animal models of MS are primarily mediated by CD4+ T cells, although the humoral immune response also contributes to the pathogenesis; (3) effective treatments seem to preferentially target T-cell responses; and (4) disease susceptibility is influenced by genes that control presentation of antigens to T cells, such as those of the major histocompatibility complex (MHC, HLA in humans).

In addition to the role of CD4+ TH1 cells, recent studies have provided evidence for the involvement of CD8+ T cells and B cells in the pathogenesis of MS (Babbe et al., 2000; Goverman et al., 2005). Clonal expansion of CD8+ T cells, a subset of T cells with cytotoxic functions, has been recently shown to be predominant over CD4+ T cell expansions both in the brain and the spinal fluid of patients with MS (Babbe et al., 2000). Furthermore, the accumulation of B-cell clones in CNS lesions and the spinal fluid of patients suggests that B cells may be chronically stimulated by CNS antigens leading to the synthesis of oligoclonal IgG (Goverman et al., 2005). Myelin-specific antibodies can contribute to myelin damage by inducing complement activation and facilitating macrophage-mediated myelin toxicity. Therefore, demyelination can be mediated through T-cells and macrophages as well as through complement activation. Myelin repair, which is limited *in vivo*, can be promoted *in vitro* with various growth factors (neurotrophin-3, platelet-derived growth factor, glial growth factor-2, others) (reviewed in Lubetzki et al., 2005).

A schematic view on the main processes that lead to autoimmune central demyelination is presented in Figures 18.2 and 18.3. Autoreactive, myelin antigen-specific T cells are part of the normal T-cell repertoire, although at low frequency. These cells are thought to be activated in the peripheral immune system

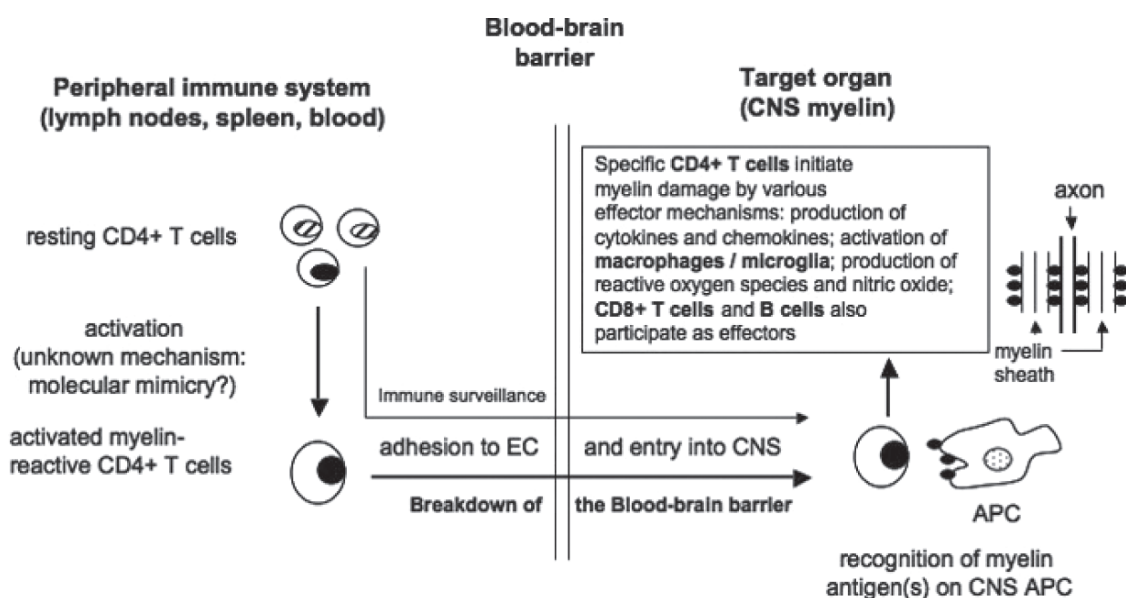

FIGURE 18.2. The immunopathogenesis of MS. A limited number of resting T cells may enter the CNS after crossing the intact blood-brain barrier (BBB). Autoreactive CD4⁺ T cells may be activated in the periphery by antigens that are structurally similar to myelin antigens (molecular mimicry). When activated T lymphocytes interact with endothelial cells (EC) of CNS venules, cell trafficking across the BBB increases. Reactivation of myelin antigen-specific T cells by local antigen-presenting cells (APC) may initiate myelin damage by several mechanisms: CD4⁺ T cell production of proinflammatory cytokines and chemokines that further recruit effector cells through an inflamed BBB; CD8⁺ T inducing cytotoxicity and chemokine production; activated macrophages producing oxygen radicals and NO (nitric oxide); deposition of myelin antigen-specific antibodies activating complement and facilitating myelin damage by activated macrophages. Resolution of inflammatory damage may be modulated by regulatory cells, that produce anti-inflammatory cytokines, and by elimination of effector cells by apoptosis.

FIGURE 18.3. Comparison of Th1 and Th2 CD4⁺ T helper cell responses. Th1 and Th2 cells can be discriminated by their ability to produce different patterns of cytokines. Based mainly on the type, dose and route of administration of antigens, the genetic background of the host, and the cytokines present in the microenvironment, naïve CD4⁺ T-cell precursors can develop into T-helper 1 (Th1) or Th2 cells. IL-12 (produced by macrophages) is the dominant factor promoting development of Th1 cells that are involved in cell-mediated immunity to intracellular pathogens and several instances of organ-specific autoimmunity. Th1 development also depends on IFN- γ (mainly produced by T cells). In contrast, early exposure of naïve CD4⁺ T-cell precursors to IL-4 results in the development of Th2 cells, which are involved in atopic and allergic reactions, and in certain types of systemic, antibody-mediated autoimmunity. Regulatory cells that produce the immunomodulatory cytokine TGF- β can modulate the development of both Th1 and Th2 cells and the immunopathology they can induce.

(lymph nodes and spleen) of MS patients by unknown mechanisms. Structural similarity of foreign antigens (such as viral peptides) and myelin proteins may lead to their cross-recognition by

myelin-reactive T cells (molecular mimicry). Activated T cells can adhere to endothelial cells in cerebral blood vessels, cross the blood-brain barrier and enter the brain parenchyma. Proteolytic

enzymes such as matrix metalloproteases cleave extracellular matrix proteins and allow T-cell entry into the CNS. Upon reactivation by recognition of myelin antigens presented by microglia astrocytes, autoreactive T cells secrete proinflammatory cytokines that may cause direct damage to myelin, such as TNF- α and lymphotoxin, and chemokines that recruit effector cells, such as other T cells and monocytes-macrophages (Figure 18.3).

Recruitment of effector cells by chemokine-regulated chemotaxis of leukocytes and monocyte-macrophages is considered to be critical for effector cell entry into, and migration within, the CNS, each of which is a critical step in the pathogenesis of immune-mediated demyelination in multiple sclerosis (Ransohoff, 1999; Sorensen et al., 1999; Charo and Ransohoff, 2006; Ubogu et al., 2006). Chemokines represent a family of chemotactic cytokines that are comprised of two major subfamilies: the C-X-C (α chemokine) subfamily that possesses two conserved N-terminal cysteine residues separated by a single amino acid, and the C-C (β chemokine) subfamily that possesses two adjacent cysteine residues. Chemokine-mediated adhesion of cells (tethering), extravasation, and infiltration is a complex process involving multiple signals and receptor-ligand interactions, and it is clear that several major steps are required: chemotaxis, adhesion and transmigration. In individuals with MS as well as in individuals without MS, most lymphocytes within the CSF are CD4+ memory T-cells in proportions that are higher than in the blood (Kivisakk et al., 2004). Such cells consistently express the chemokine receptor CCR7 and most also express CXCR3. Within perivascular MS lesions, however, CXCR3-expressing T-cells are commonly found while CCR7 expression is down-regulated (Sorensen et al., 1999).

Analysis of both CSF and brain tissue from individuals with MS has revealed consistent patterns of chemokine expression that distinguish not only MS patients from neurologically normal controls, but also stable MS patients from those undergoing acute relapses (Ransohoff, 1999; Sorensen et al., 1999). Levels of CXCL10 (CXCR3 ligand) and CCL5 (CCR5 ligand) were undetectable in CSF from more than 90% of control patients, but were elevated in more than 50% of CSF specimens from individuals with MS clinical attacks (Ransohoff, 1999). Furthermore, levels of CCL2 were significantly reduced during acute attacks, while levels of several other chemokines (CCL3, CXCL9, CXCL1, and CXCL8) were not significantly altered. This represented the first demonstration of CNS chemokine alterations related to MS clinical disease activity, and it suggested that TH-1-mediated T-cell signaling clearly plays a role in MS pathogenesis. As a result of such studies in MS patients, clinical trials with selected chemokine receptor antagonists have been undertaken (e.g. a CCR2 antagonist) (Charo and Ransohoff, 2006).

Another critical determinant in the cascade of events leading to MS lesion development is antigen presentation. Antigen presenting cell (APC)/T-cell activation involves at least four major processes: (1) Molecular mimicry, (2) Epitope spreading, (3) Bystander activation, and (4) Cryptic antigen

presentation. These mechanisms are not mutually exclusive and each is believed to contribute to the pathogenesis of MS. Molecular mimicry, as described earlier in this chapter, is a phenomenon wherein foreign antigens have enough similarity to the host's endogenous proteins to elicit an autoimmune response. In 1985, it was demonstrated that injection of rabbits with a Hepatitis B virus peptide containing six amino acids in common with MBP induces encephalitis through a cross-reactive immune reaction against MBP (Fujinami and Oldstone, 1985). Since this early observation, the concept of molecular mimicry has been expanded to include involvement of sequence homology, sharing of conserved TCR (T cell receptor) and MHC contact motifs between peptides, additive stimulatory contributions, and structural homology (reviewed in Sospedra and Martin, 2006). Of interest, regions of sequence and structural homology between MBP and two human herpesviruses that are candidate etiologic agents for MS, HHV-6 and EBV have recently been identified (Tejada-Simon et al., 2003; Holmoy et al., 2004).

Epitope spreading occurs when the immune response to a target antigen extends to other epitopes present on the cell that are involved in the primary immune response. These additional epitopes may be within the same molecule (intramolecular) or in different molecules (intermolecular) (Vanderlugt and Miller, 2002). T-cell activation and functional epitope spreading require costimulation via CD28-CD80/86 or CD154-CD40 interactions (Vanderlugt and Miller, 2002). The pathological consequences of epitope spreading have been demonstrated in several mouse models for MS, including Experimental Autoimmune Encephalitis (EAE) and Theiler's Murine Encephalitis Virus (TMEV) induced demyelinating disease (discussed later in this chapter). In EAE, priming with the PLP immunodominant epitope results in an acute clinical episode that is followed by a relapsing remitting disease course that is mediated by PLP specific TH-1 cells and correlates with intramolecular epitope spreading (Vanderlugt and Miller, 2002). In Theiler's virus-induced demyelinating disease, disease onset occurs after infection with TMEV, resulting in a chronic disease course. As the disease progresses, TH-1 responses to TMEV persist. In addition, myelin debris released as a result of the initial tissue damage induces CD4+ TH-1 responses to myelin epitopes starting with PLP and, in late stages of the disease, spreading to MBP and MOG (myelin oligodendrocyte glycoprotein) (Vanderlugt and Miller, 2002).

Bystander activation activation of autoreactive cells through nonspecific inflammation and induction of inflammatory cytokines and chemokines is also of pathological consequence in MS. It has been suggested that bystander activation, induced by persistent virus infection or primed by molecular mimicry may activate autoreactive T-cells specific for the CNS (McCoy et al., 2006). Finally, cryptic antigens may also play a role in immune activation. In other immune-mediated diseases such as Chronic Lymphocytic Thyroiditis and Chagas Heart Disease, exposure of cryptic epitopes leads to the activation of autoimmune cells and further contributes to

the pathogenesis (Rose and Burek, 2000; Leon and Engman, 2003). Similarly, it has been suggested that myelin destruction leads to the exposure of cryptic axonal antigens that are normally shielded from immune surveillance by the tightly sealed paranodal loops of myelin. The exposure of these cryptic antigens may activate auto-reactive T-cells and the production of anti-axolemmal antibodies. It has been suggested that these anti-axolemmal antibodies induce neurodegeneration, prevent remyelination and contribute to the axonal loss that correlates with functional loss in MS. (DeVries, 2004).

18.5. Animal Models of MS

18.5.1. Experimental Autoimmune Encephalomyelitis (EAE)

While no single animal model completely recapitulates all features of MS, Experimental autoimmune encephalomyelitis (EAE, Table 18.2) is the most widely used. Rivers' seminal investigation into the iatrogenic human disease, postvaccinal encephalomyelitis was critical in the development of field of EAE (Rivers et al., 1933). Early models of EAE involved the induction of inflammatory demyelinating lesions in experimental animals by immunization with brain or spinal cord tissue (Rivers et al., 1933). Current models rely on active immunization with myelin antigens (myelin basic protein (MBP), myelin associated glycoprotein (MAG), proteolipid protein (PLP) or myelin-oligodendrocyte-glycoprotein (MOG)) in adjuvant or by adoptive transfer of encephalitogenic, myelin antigen specific T cell lines or clones (passive immunization) (Ebers, 1999; Lassmann and Wekerle, 1998; Ercolini and Miller, 2006). Although mouse and rat models are the most commonly used, EAE can be induced in a variety of susceptible animals including guinea pigs, rabbits, pigs, and monkeys.

The clinical signs of EAE reflect the acute inflammatory responses developing in the brain and spinal cord: hindlimb and tail paralysis, quadriparesis, ataxia, abnormal righting responses, and sometimes incontinence (Lublin, 1996). These episodes, whether associated with active or passive immunization, are associated with infiltration of myelin-specific inflammatory TH1 CD4+ T-cells into the CNS (McRae et al., 1992). The disease can be either monophasic (with a single paralytic episode followed by recovery), relapsing-remitting (with repeated cycles of paralysis interrupted with partial or full recovery), or chronic (initial symptoms either stabilize or progress) (Ercolini and Miller, 2006). These later two clinical courses more closely resemble the natural history of MS symptoms. In EAE, TH-1, proinflammatory cytokines contribute to tissue destruction directly, upregulate expression of MHC I and II within the CNS, and lead to macrophage and microglial activation. Paradoxically, treatment with the proinflammatory cytokines IFN- γ and TNF- α is protective in EAE, while similar treatments lead to disease exacerbation in MS (Krakowski and Owens, 1996).

EAE is traditionally regarded as a prototypic TH-1 CD4+ T-cell mediated autoimmune disease of the CNS. However, other cells of the immune system play important roles in the neuropathogenesis of this disorder. Defining the precise role of various cell types in EAE is complicated by the diverse and heterogeneous nature of EAE model systems. Recently, a new class of T-cells, TH-17 cells, has been shown to regulate inflammation in EAE. This unique subset of T helper cells produce IL-17 and develops along a pathway that is distinct from that of TH-1 and TH-2 cell differentiation (Park et al., 2005). It has been demonstrated that neutralization of IL-17 with IL-17-receptor-Fc-protein or an IL-17 monoclonal antibody ameliorates the disease course of EAE (Hofstetter et al., 2005). The production of IL-17 requires upstream activation of IL-23, and neutralizing antibodies specific for

TABLE 18.2. Features of EAE and MS.

Feature	EAE	MS
CNS signs	+++	+++
Relapsing disease	++	+++
Perivascular inflammation	+++	+++
Cellular infiltrate	CD4+ T-cells, MOG-specific CD8+ T-cells	CD8+ T-cells, CD4+ T-cells, B-cells
Demyelination	+, +++, perivenous	+++; diffuse
Remyelination	++	++
Immunogen	MBP, PLP, MOG, others	Unknown
CSF immunology	Antibodies to myelin antigens	Rarely find antibodies to myelin antigens; OCB antigens unknown
Genetic predisposition	++	++
Linked to MHC	++	++
Response to immunomodulation	+++	++

IL-23 also ameliorate disease progression in EAE (Chen et al., 2006). In addition, EAE is significantly suppressed in IL-17 knockout mice further indicating the importance of IL-17 in the pathogenesis of EAE (Komiyama et al., 2006).

In addition to T-cells, other cell types have been found to play important roles in EAE induced by both active immunization and adoptive transfer. CD8⁺ cells play a variable role in EAE. In the absence of CD8⁺ T-cells, more severe disease is observed. However, MOG-specific CD8⁺ T-cells have been observed and are capable of transferring EAE in SCID mice. In addition, H2k MBP-specific CD8⁺ T-cell clones recognizing the peptide fragment MBP 79–87 (Huseby et al., 1999). B cells are generally believed to be dispensable in EAE as B-cell deficient (B10.PL × SJL/J) mice develop EAE after immunization (Dittel et al., 2000). In B6 mice, the absence of B-cells exacerbates EAE suggesting a protective role for these cells. However, MOG-induced EAE is aggravated by administration of anti-MOG antibodies, suggesting an important role for the humoral response in some models of EAE.

EAE has been used extensively to gain insight into almost every aspect of the neuroimmunology and neuropathology of MS. In addition, the majority of therapies that are either routinely used or currently under development for MS were initially developed in EAE. However, EAE has received criticism as an incomplete model of MS (Sriram and Steiner, 2005). It has been suggested that EAE is a model of acute CNS inflammation/demyelination such as acute disseminated encephalomyelitis (ADEM) rather than a true counterpart for MS. Critical differences between MS and EAE include differences in lesion composition (CD4⁺ cells dominate in EAE while in the inflammatory MS lesion macrophages and CD8⁺ cells are frequently observed), lesion location, affect of immunotherapies (e.g. IFN- γ can ameliorate EAE, but increases exacerbations in MS, IFN- β decreases relapse rate in MS, but can worsen EAE), and the observation that the significant axonal damage observed in MS is absent in most models of EAE (Sriram and Steiner, 2005). Nevertheless, the three dominant, FDA approved treatment modalities for MS (Copolymer-1, IFN- β , and Natalizumab) were all developed in EAE which underscores the great utility of this model in spite of its imperfections (Steinman and Zamvil, 2006).

18.5.2. Viral Models of MS

18.5.2.1. Theiler's Murine Encephalomyelitis Virus

There are two major virus induced, murine models of MS: Theiler's Murine encephalomyelitis viruses (TMEV) and mouse hepatitis virus (MHV). Each is a naturally occurring rodent virus that infects the CNS and induces demyelination in genetically susceptible hosts. Theiler's Murine encephalomyelitis viruses (TMEV) are members of the *Picornaviridae* that naturally cause neurologic and enteric diseases in mice (Rodriguez et al., 1987). Several strains of TMEV are capable of inducing paralysis in susceptible rodents. Interestingly it is the persistent, avirulent strain that causes chronic disease;

members of the GDVII subgroup grow to high titers and cause a fatal polioencephalomyelitis, while the Daniels (DA) strain and other members of the Theiler's original (TO) subgroup grow to relatively low titers and induce a chronic inflammatory demyelinating disease of the spinal cord (Rodriguez and Roos, 1992). In the later case, the disease is bi-phasic with an acute encephalitic phase followed by late chronic demyelinating disease, associated with mononuclear infiltrates and demyelinating lesions (Murray et al., 2000).

Several features of TMEV-induced CNS disease including clinical, genetic, and histopathological similarities with MS make this a relevant experimental model. Chronic and/or relapsing remitting paralytic symptoms are observed in both MS and TMEV encephalomyelitis. In addition, natural infection with the TO strains of TMEV progresses to CNS infection and the development of chronic, progressive neurologic disease in a small percentage of infected mice and intracerebral injection only leads to CNS disease in some mouse strains, suggesting a genetic component to the disease. Both diseases are under multigenic control and susceptibility is associated with genes involved in the immune response including MHC genes (Borrow et al., 1992). In addition, TMEV encephalomyelitis, like MS, is a predominantly TH-1 mediated disorder. A strong, TH-1 response has been demonstrated during the acute phase (Chang et al., 2000) and, in some mouse strains, during the chronic phase (Chang et al., 2000). Recently, matrix metalloproteinases, which degrade extracellular matrix molecules and are involved in demyelination processes, were demonstrated to be upregulated in chronic demyelinating Theiler's Murine encephalomyelitis (Ulrich et al., 2006). Lastly, the cellular makeup of the mononuclear infiltrates in both diseases consists primarily of T lymphocytes, monocytes, and macrophages (the primary host cell of the virus) and demonstrate striking similarities with MS lesions. It has been demonstrated that CD8⁺ T cells are critical in the prevention of TMEV mediated demyelination and that CD4⁺ cells are important in the synthesis of neutralizing antibodies. In addition, as TMEV encephalomyelitis is caused by latent and persistent infection of the CNS, it makes this an intriguing model for MS, a disorder for which an infectious etiology is suspected. Recently, recombinant TMEV encoding a mimic peptide for PLP that is naturally expressed by *Haemophilus influenzae* has been described (Olson et al., 2005). Infection with this recombinant virus results in early disease onset. These studies support molecular mimicry as a viable hypothesis in MS.

18.5.2.2. Murine Hepatitis Virus

Murine hepatitis virus (MHV) is a murine coronavirus that infects the liver. Two strains of MHV, JHM and MHC-A59 are neurotropic variants that are frequently used in studies of MHV infection of the CNS (Matthews et al., 2002). Both viruses readily infect oligodendrocytes, astrocytes and neurons (Matthews et al., 2002). After acute infection, the animals develop a chronic progressive neurologic disease characterized by a single major episode of demyelination

and accompanied by hind limb paresis, paralysis, and ataxia. Recovery is mediated by CNS and, sometimes, peripheral nerve remyelination (Matthews et al., 2002). In this model, it is believed that demyelination results from both immune-mediated and direct viral destruction. CD8⁺ T-cells mediate CNS disease and MHV induces both TH-1 and TH-2 cytokines. Interestingly, partial depletion of CD4⁺ and CD8⁺ cells does not eliminate chronic demyelination. In addition, humoral immunity is critical for both clearance of the virus and establishment of persistent infection. Chronic lesions in MHV are found throughout the spinal cord and are similar to chronic lesions in MS. As the disease progresses, lymphocytic infiltration diminishes while demyelination and astrogliosis increases. Unlike TMEV, no autoimmune reaction against brain antigens has been described in the MHV model.

18.6. Recent Advances in the Neuroimmunology of MS

18.6.1. CD4⁺CD25⁺ Regulatory T-Cells (T Regs)

While CD4⁺ T cells are traditionally regarded as pathogenic in MS, CD4⁺CD25⁺ regulatory T-cells (T regs) have emerged as major players in inhibiting autoimmune disease in humans and in rodent models. Suppression by T regs is critical in preventing autoreactive T-cells from causing autoimmune disorders and in inducing peripheral tolerance. Accordingly, depletion of T reg cells leads to the onset of systemic autoimmune disorders in mice. Although T reg cells exist in the same frequency in MS patients, the effector function of these cells are significantly impaired in relapsing-remitting MS patients (Viglietta et al., 2004). Interestingly, T reg cell function and expression of the T reg-specific transcription factor, FOXP3, is normal in chronic progressive MS patients (Venken et al., 2006). In EAE, suboptimal T-cell stimulation results in significant pathology and delayed recovery upon depletion of CD4⁺CD25⁺FOXP3⁺ cells, indicating that these cells are highly important in raising the threshold for triggering autoreactive T-cell responses (Stephens et al., 2005). In the future, monitoring the effects of immunomodulatory therapies on T reg cells will help define the role of these cells in autoimmune disorders and lead to the development of novel therapies for MS. Currently, a novel T-cell receptor peptide-based immunotherapy (NeuroVax) that restores normal function of FOXP3⁺ T regs is entering phase II clinical trials (Darlington, 2005).

18.6.2. B Cell Responses in MS

While the presence of OCB in MS has long been appreciated, recent studies have re-examined the role of B-cells in MS. Antibody binding studies have demonstrated that binding to a neuronal cell line was increased in chronic progressive

MS patients compared to relapsing remitting multiple sclerosis patients and other inflammatory CNS disease controls (Lily et al., 2004). This approach could lead to the identification of cell surface autoantigens that may be involved in mediating demyelination or neuronal damage. In another study, proteomics technology was used to characterize autoantibodies directed against candidate antigens, in EAE, MS patients, and controls (Robinson et al., 2003).

In addition, antibodies may play a beneficial role in MS by skewing the immune system away from a TH-1 biased response and toward a TH-2 cytokine pattern or by fostering myelin repair. It has been demonstrated that IgM antibodies to CNS antigens enhance remyelination in MS (Sospedra and Martin, 2005). The beneficial effect of pooled intravenous Ig in MS therapy supports a beneficial role for antibodies in MS. It is believed that this beneficial effect occurs through several mechanisms including inactivation of cytokines, Fc-receptor blockade, blocking of CD4 and MHC, and modulation of apoptosis (Sospedra and Martin, 2005).

18.7. Other Demyelinating Diseases of the CNS

Several other demyelinating disorders such as neuromyelitis optica (NMO/Devic's disease), transverse myelitis, acute necrotizing myelitis and Foix-Alajuanine Syndrome share some features with multiple sclerosis but in some cases represent distinct pathological entities. Neuromyelitis optica that is characterized by a generally acute, severe clinical necrotizing demyelinating syndrome that primarily affects the optic nerves and spinal cord. Unlike classical MS-associated demyelination, the neuromyelitis optica lesions are characterized by necrosis and vascular proliferation associated with a marked elevation of the CSF white blood cell count (>100 wbc/mm³; often neutrophils) and protein level. OCBs are usually not found in the CSF. Neuromyelitis optica is more often monophasic (35%) than is MS. Pathologically, it is characterized by gray and white matter necrosis, infiltration of macrophages, eosinophils and neutrophils, and deposition of IgM and IgG with perivascular complement activation (Kerr and Calabresi, 2005). Recent discovery of an association between the presence in the serum of an IgG antibody against aquaporin 4, a mercurial-insensitive water channel protein concentrated in astrocytic foot processes at the blood-brain barrier, in patients with neuromyelitis optica, has led to the investigation of an anti-B cell (anti-CD20) humanized monoclonal antibody as treatment for this disease (Pittock et al., 2006; Cree et al., 2005; Lennon et al., 2005).

Demyelinating syndromes such as optic neuritis and transverse myelitis have clearly defined relationships with MS and are felt to represent the typical demyelinating lesions found in the white matter of the brain in MS. Optic neuritis is frequently the initial clinical manifestation of MS, and is typically heralded by a decline in vision associated with eye pain over

a 7- to 10-day period (Frohman et al., 2005). Approximately 50–70% of individuals with optic neuritis have periventricular white matter abnormalities consistent with demyelination by MRI assessment, and up to 88% of these individuals develop definite MS within 14 years of presentation of optic neuritis (Brex et al., 2002). Patients respond well to acute corticosteroid treatment as well as prophylactic treatment with IFN- β , similar to individuals with MS (Balcer, 2006). Transverse myelitis refers to the clinical syndrome of partial or complete spinal cord dysfunction resulting from inflammatory demyelination. With partial cord dysfunction, the risk of development of MS is as high as 70%, but it is less than 15% when spinal cord function is completely lost (Coyle, 2000). Transverse myelitis is associated with marked CSF elevations of IL-6, which in model systems can activate inducible nitric oxide synthase (iNOS) in the spinal cord, possibly leading to neuronal injury (Kerr and Calabresi, 2005).

The Foix-Alajuanine Syndrome and acute necrotizing myelitis are pathologically and clinically distinct from demyelinating syndromes associated with MS. Foix-Alajuanine Syndrome is a rare cause of myelopathy (spinal cord dysfunction) that is caused by a dural arteriovenous malformation of the spinal cord (Mishra and Kaw, 2005). It is often confused with transverse myelitis or acute necrotizing myelitis. Rather than immune-mediated cord damage, the syndrome is characterized by subarachnoid hemorrhages that result in severe local arachnoid fibrosis and associated thrombosis of local blood vessels. Patients are usually over 50 years of age, and suffer a slow progression to paraplegia. Acute necrotizing myelitis is distinct from typical demyelinating spinal cord involvement in MS. It is associated with coagulative necrosis of both gray and white matter, infiltration of T-cells and macrophages, a high CSF protein level (>500 mg/dl), and absence of OCB in the CSF, thus distinguishing it pathologically from MS, but suggesting important similarities with neuromyelitis optica (Katz and Ropper, 2000). Clearly, better understanding of the various forms of immune-mediated myelitis (neuromyelitis optica, transverse myelitis, necrotizing myelitis) will likely reveal both common and unique features of each that will guide the development of newer therapies for MS and other demyelinating diseases.

Summary

The pathogenesis of MS is a complex immune-mediated process that can likely be triggered by multiple antigens presented within the CNS, which can elicit T-cell and B-cell responses that promote myelin damage and the resulting neuronal damage. Antigenic responses are thought to be induced and amplified in some cases through molecular mimicry, epitope spreading, bystander activation of antigen-presenting cells, and by cryptic antigens that are normally shielded from presentation. Epidemiological evidence suggests that environmental (infectious) agents can trigger such responses in genetically

susceptible hosts, based upon strong associations between geographic residence, occurrence of MS and presence of certain MHC I and II alleles within the affected population. Animal models of induced CNS demyelination (EAE, neurotropic viruses; TMEV, MHV) have largely confirmed that presentation of myelin-associated antigens within the CNS as well as CNS virus infection can elicit strong MS-like T-cell and B-cell responses and MS-like neurological dysfunction in animal hosts. Within the brains of MS patients, pathological studies confirm the infiltration of CD4+ and CD8+ T-cells and macrophages, as well as deposition of IgG and complement to varying degrees in defined subtypes of MS plaques. Along with such infiltrates, robust expression of proinflammatory cytokines and chemokines within the brain and CSF is consistently demonstrated, and such factors can promote the recruitment of reactive T cells and monocytes from the periphery that can amplify inflammatory responses. Clinical responses to different immunomodulating therapies in MS patients further support roles for T-cell- and B-cell-mediated immune dysregulation in MS pathogenesis. Future MS therapies will likely target not only activated lymphocytes (T-cells, B-cells, Tregs) and macrophages, but also the neurons that are rendered vulnerable by associated myelin damage.

Review Questions/Problems

1. Which of the following statements is true about gender differences in MS?

- a. Men are more likely than women to develop MS.
- b. Women are likely to have a later age of disease onset.
- c. Women have a more rapid disease progression
- d. Men with MS have a worse prognosis.

2. The geographic distribution of MS:

- a. follows an east-west gradient
- b. increases at higher altitudes
- c. increases with distance from the equator
- d. is skewed toward northern latitudes in both hemispheres

3. An environmental component in the etiology of MS is supported by:

- a. the geographic distribution of MS
- b. migration studies
- c. relatively low concordance (25–30%) in identical twins
- d. reports of MS epidemics
- e. all of the above

4. Which of the following immune abnormalities are not associated with MS?

- a. overexpression of IL-10
- b. increased expression of adhesion molecules
- c. presence of oligoclonal bands in the CSF
- d. increased TNF- α expression preceding clinical relapse

- 5. Which immunomodulatory therapies are frequently used in MS?**
- IFN- β
 - IFN- γ
 - Copolymer-1
 - corticosteroids
 - all of the above
 - a, b & d
- 6. Oligoclonal bands represent:**
- Immunoglobulins directed against recently identified myelin epitopes in MS
 - Immunoglobulins directed against unknown CNS epitopes in MS
 - Immunoglobulins that have been shown to deposit around demyelinated plaques in MS
 - Immunoglobulins often detected in the serum of individuals with MS
 - b & e
- 7. MS plaques have been histologically demonstrated to include:**
- infiltration of CD8+ T-cells
 - infiltration of CD4+ T-cells
 - infiltration of B-cells
 - IgG deposition
 - Complement deposition
 - all of the above
 - a & b
 - a, b & c
 - a, b, c & d
- 8. Which of the following statements is false?**
- In MS plaques perivenular infiltrates contain mainly mononuclear and lymphocytic cells, including CD8+ T-cells, CD4+ T-cells, macrophages, and B-cells.
 - In the EAE model, the primary infiltrating cell is the CD8+ T-cell.
 - Effective MS treatments generally target T-cell responses
 - In both EAE and MS, disease susceptibility is influenced by genes that control presentation of antigens to T-cells.
- 9. In the pathogenesis of MS, molecular mimicry implies:**
- Receptors mediating T-cell migration have overlapping function, i.e., they can mimic each other's ligand specificity.
 - Immune modulating chemokines or cytokines can mimic the molecular functions of each other.
 - Structural similarity of foreign antigens and myelin protein components may lead to cross-recognition by myelin-reactive T-cells.
 - Suppression of selected T-cell responses can have a global impact on both CD4+ and CD8+ T-cells.
- 10. Comparison of EAE with MS shows the following:**
- Both demonstrate monophasic, relapsing, and chronic progressive clinical courses
 - Perivascular inflammation is common in both.
 - Demyelination is diffuse throughout the brain in both.
 - All of the above
 - a & b
- 11. Which viruses have been associated with an increased risk for development of MS?**
- Herpes simplex (HSV)
 - Human herpes virus-6 (HHV-6)
 - Measles
 - Varicella-zoster
 - Rubeola
 - Epstein-Barr
 - All of the above
 - a, b, c & f
- 12. Among the viruses listed in question 11, which ones have been demonstrated to be causative agents in MS?**
- a
 - b
 - c
 - d
 - e
 - f
 - all of the above
 - none of the above
- 13. Which features of Theiler's virus-induced CNS disease make it a useful model for MS?**
- The animals develop chronic and/or relapsing paralytic symptoms.
 - Both diseases are under multigenic control by immune response genes.
 - Both are predominantly TH-1 mediated disorders.
 - B-cell infiltration predominates in Theiler's virus induced disease.
 - a
 - a & b
 - a, b & c
 - a, b, c & d
- 14. Apoptosis of which cell type is a histological hallmark of at least one pathologic subtype of MS plaque?**
- neuron
 - astrocyte
 - oligodendrocyte
 - macrophage
 - none of the above
- 15. Optic neuritis is the presenting symptom in what percentage of MS patients?**
- 10%

- b. 20%
- c. 30%
- d. 40%
- e. 50%

16. The diagnostic criteria for MS:

- a. Depend upon the demonstration of white matter abnormalities in the brain or spinal cord by MRI.
- b. Require evidence for the presence of neurological dysfunction for the diagnosis in all cases.
- c. Require that there is no better explanation (other than MS) for the clinical presentation.
- d. None of the above
- e. a, b & c
- f. a & c
- g. b & c

Guillain-Barré Syndrome, Chronic Inflammatory Demyelinating Polyradiculoneuropathy, and Axonal Degeneration and Regeneration

Ralf Gold and Klaus V. Toyka

Keywords Autoantibodies; Axonal damage; Chronic inflammatory neuropathy; Gangliosides; Guillain-Barré syndrome; Immune neuropathy; Myelin; Nerve conduction; Neuritis; Neurotrophin

19.1. Introduction

Guillain-Barré syndrome (GBS) and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) are acquired demyelinating diseases of the peripheral nervous system (PNS), characterized by progressive or relapsing proximal and distal muscle weakness with possible sensory loss (Saperstein et al., 2001; Hughes and Cornblath, 2005). Historically GBS was described in 1916 in two French soldiers as an acute, postinfectious paralysis with elevated CSF protein but without cells. At that time also epidemics of poliomyelitis have occurred producing “Landry paralysis”, as a direct consequence of enterovirus infection, and in contrast to GBS is usually asymmetrical and associated with CSF pleocytosis. In the following decades, with the availability of electrodiagnosis the clinical hallmarks of GBS have been described more precisely. Estimated annual disease incidence in industrialized countries is up to 2/100,000. In contrast to CIDP, about 50% of GBS cases are linked with preceding infections, typically diarrhea caused by *C. jejuni* (Enders et al., 1993) or infections of the respiratory tract (Hadden et al., 2001). In GBS acute respiratory failure or cardiac arrhythmias due to dysfunction of the autonomic nervous system cause at least 3% mortality even in specialized centers, especially in elderly patients with rapid disease progression and those suffering from multimorbidity (Hughes and Cornblath, 2005). In addition, both in GBS and CIDP, residual symptoms and chronic fatigue may lead to long-lasting disability in about half (Merkies et al., 1999).

The last decade has seen remarkable progress in understanding cellular and molecular pathways that cause autoimmune damage in these disorders of the PNS (see reviews in Gold et al., 2003, 2005; Kieseier et al., 2004). Based on the observations that a significant proportion of patients with CIDP

are responsive to immunotherapy and that an inflammatory response is observed at sites of active disease (Schmidt et al., 1996; Sommer et al., 2005), it is generally accepted that GBS and CIDP are autoimmune disorders with myelin as the likely target for the immune response. There is increasing evidence that GBS and CIDP have heterogeneous pathomechanisms. The dominant subtype is the acute inflammatory demyelinating form (AIDP), a classical demyelinating disease, but an increasing number of axonal variants has been described after the first series linked to preceding infections in China with acute motor axonal neuropathy (AMAN) (McKhann et al., 1991). Whilst first data seemed to associate axonal damage to preceding *C. jejuni* infection, especially with Penner 19 strain (Ho et al., 1995), these regional specificities could not be confirmed in the largest multicenter GBS-study performed to date (Hadden et al., 1998, 2001). Acute motor-sensory axonal neuropathy (AMSAN) is clinically and electrophysiologically similar to AMAN, but has a detectable sensory involvement. Thus, there is probably no single or unique mechanism that leads to axonal damage, but several immunological components will be discussed which may contribute to neuronal dysfunction and degeneration. This heterogeneity of the disease is further underscored by the variant of GBS, the Miller Fisher syndrome (MFS), where cranial nerves and caudal spinal roots are involved, and the disorder is strongly linked with anti-ganglioside GQ1b immunoreactivity.

Chronic inflammatory demyelinating polyneuropathy (chronic polyneuritis, CIDP) characteristically presents as symmetrical weakness, with some impairment of distal sensation. By electrophysiology both motor and sensory nerves are affected with slowing of nerve conduction velocity, especially in proximal nerve segments as reflected by abnormal F-wave examination. Cranial nerves may be involved, but less frequently than in GBS. The disease course may either be relapsing-remitting or stepwise progressive. If the initial attack of CIDP is subacute, disease progression up to reaching a plateau level is longer than 8 weeks. The diagnosis is supported by an elevated CSF protein, and inflammatory demyelination in sural nerve biopsy.

19.2. Experimental Models

For many aspects of both diseases, the various models of experimental of allergic/autoimmune neuritis (EAN) have helped us to better understand the immunological mechanisms (see review in Gold et al., 2005). The monophasic EAN of the Lewis rat has its greatest advantage for defining pathogenetic hallmarks and establishing innovative therapeutic principles, similar to the chronic EAN in dark agouti rats. Upon immunization with increasing doses of the neuritogen or when antigen-specific T cell lines are used for adoptive transfer (AT-EAN), many clinical and electrophysiological signs of the human diseases could be reproduced (Heininger et al., 1986; Hartung et al., 1988). In particular, a profound and rapidly evolving nerve dysfunction occurred dose-dependently which correlated with increased axonal damage due to Wallerian degeneration. In the high-dose adoptive transfer model, most likely endoneurial ischemia resulting from severe inflammation and edema was an admixed and critical pathogenic mechanism.

Progress in molecular biology has allowed generation of an increasing number of transgenic mice, which are typically on the genetic background of C57BL/6. For these mouse strains defined peptides of the myelin protein P0 have been described as neuritogenic (Miletic et al., 2005; Visan et al., 2004). Besides the acute and chronic autoimmune models induced by immunization or adoptive transfer of T cells, the immune system has been shown to contribute to disease progression and expression in inherited myelinopathies, which was elucidated by Martini and colleagues (see review in Martini and Toyka, 2004). When the immune system was paralyzed by backcrossing the P0 deficient mice on C57BL/6 background with RAG deficient knockout mice, a remarkable delay of myelin pathology was observed within six months. This was not limited to demyelination, but also axonal damage was reduced which may reflect trophic aspects of the axon-Schwann cell unit. Recent *in vitro* studies have confirmed that indeed dorsal root ganglia cultures from a rat model for Charcot Marie Tooth disease undergo axonal atrophy over a period of time (Nobbio et al., 2006). This model may be utilized to study the molecular changes underlying demyelination and secondary axonal impairment, in particular in the chronic disorders such as CIDP. As axonal damage may occur after just 3 months and tissue cultures represent a strictly controlled environment, this model may also be ideal for testing neuroprotective therapies.

19.3. Pathogenesis of Axonal Damage in GBS and CIDP

The presence of prominent demyelination, with “onion bulb” formations in chronic disease, and of perivascular inflammatory infiltrates are both hallmarks of CIDP pathology (Bosboom et al., 2001b; Sommer et al., 2005), although they may not always be

found on small nerve samples from human biopsies. The “onion bulb” formation is a manifestation of excessive Schwann cell processes and is often produced by segmental repetitive demyelination and remyelination (Krendel et al., 1989; Bosboom et al., 2001a). As the disease progresses, secondary axonal degeneration becomes more established, but it also may occur early in the disease course (Dalakas, 1999). This is very similar to the situation in multiple sclerosis (MS), where the work of Trapp’s group (Trapp et al., 1998) quantified progressive axonal damage in late disease stages, complemented by the recent findings of axonal damage in early biopsied MS lesions (Kuhlmann et al., 2002). The precise mechanisms that lead to demyelination and (early) axonal damage in the CNS and PNS are not known, but are thought to be mediated by both cellular and humoral immune factors. In MS, axonal damage has been associated with cytotoxic CD8 T cells (Neumann et al., 2002), nitric oxide (NO) (Smith et al., 2001) and free oxygen radicals. Similar observations relate to the detrimental role of focal nitric oxide in the PNS (Kapoor et al., 2003) although in the whole animal, the opposite effect has also been described (Kahl et al., 2003).

19.3.1. Neurotrophic Factors and Survival in the Inflamed Nervous System

Experimental models have revealed that the immune system is not the only denominator for the extent of damage in the inflamed nervous system. In EAE the neurotrophic cytokine CNTF (ciliary neurotrophic factor) has clear neuroprotective role on survival of oligodendrocyte progenitor cells and mature oligodendrocytes (Linker et al., 2002). This in turn leads to enhanced demyelination in mice where CNTF was lacking, and ultimately was associated with axonal damage. In contrast to other neurotrophins CNTF does not have an effect on immune cells, so that these findings could be attributed only to neuroprotection. A retrospective study in MS patients gave additional evidence that CNTF is also relevant in the human disease MS: those MS patients which have a genetic deficiency of CNTF appeared to exhibit earlier motor symptoms and a more severe disease course (Giess et al., 2002).

Since CNTF has also been described as lesion factor in the PNS (Sendtner et al., 1992), it seemed attractive to substitute neurotrophic factors by exogenous administration. This is a major problem with CNTF, which is mostly absorbed in the liver upon *s.c.* injection (Dittrich et al., 1994), and did not show protective effects on regeneration of the inflamed nerve in the Lewis rat EAN model (Gold et al., 1996). In contrast LIF (leukemia inhibitory factor), another family member of this IL6-cytokine group turned out to augment survival of oligodendrocytes during EAE (Butzkueven et al., 2002) as confirmed by signaling studies and molecular histology. The administration of LIF had positive effects on the disease course both in a preventive and in a therapeutic setting. Yet LIF also interferes with the immune system and affects T cell priming (Linker, Gold submitted for publication).

Studies with s.c. administration of the neurotrophin BDNF have been performed in Lewis rat EAN (Felts et al., 2002). Treatment of Lewis rats with BDNF (10 mg/kg day) did not significantly affect the neurological deficit, nor significantly improve survival, motor function or motor innervation. The weight of the urinary bladder was significantly increased in control animals with EAN, but remained similar to normal in animals treated with BDNF. These results speak for a very limited effect of exogenous administration of BDNF. For thorough interpretation it would be required that pharmacological tracking studies are performed to verify the effect of BDNF on the target organ.

Thus, it is currently not clear how local factors in the target tissue modulate recovery from an immune attack in the PNS. As yet unknown genetic susceptibility factors may modulate the inflammatory process itself and the response of axons and of myelinating Schwann cells to the inflammatory assault. As an example, axonal degeneration occurring in autoimmune neuropathies clearly affects prognosis (Dalakas, 1999). Indeed, parallel expression of neurotrophic factors and their receptors in CIDP may reflect such survival mechanisms in the PNS (Yamamoto et al., 2002).

19.3.2. Cellular Immune Factors

Inflammatory infiltrates as seen in nerve biopsies, consisting primarily of macrophages (Sommer et al., 2005) and T cells (Schmidt et al., 1996), suggest that a T-cell-mediated delayed hypersensitivity reaction directed toward myelin antigens is a probable cause of inflammatory tissue damage in GBS and CIDP. Inflammatory immune reactions are coordinated by a number of soluble chemical mediators and selective adhesion molecules, including the following: direct differentiation and migration of T cells; translocation of T cells across the vascular endothelium; stimulation of protease release; and recruitment of macrophages and additional T cells to sites of inflammation (see review in Gold et al., 2003). In both CIDP and MS, dysregulation of these chemical mediators (i.e., cytokines, chemokines, and adhesion molecules) is postulated to play a role in the breakdown of the blood-nerve and blood-brain barriers, respectively. Furthermore, dysregulation of chemical mediators may be responsible for aberrant trafficking of T cells into the PNS and perpetuation of inflammatory responses that lead to demyelination. In both the PNS and CNS, inflammatory T cells are eliminated by apoptosis, occurring either during the natural disease course or after treatment with glucocorticosteroids (Zettl et al., 1995).

19.3.3. Humoral Immune Factors

In the last decades, postinfectious molecular mimicry has been postulated as the foremost putative mechanism underlying GBS. This implies that antigenic determinants are shared between an infectious agent and the peripheral nervous system. Thus the initial antigenic stimulation by the infectious agent results

in a secondary immune response directed against the nervous system. Several microbial organisms share antigens with the nervous system: *C. jejuni* serotypes O19 or Lior 11 have lipopolysaccharides (LPS) or lipo-oligosaccharides with ganglioside-like structures (causing anti-GM1 or anti-GQ1b immunoreactivity). In addition, *Hemophilus influenza* has homologies with GM1 and GT1a, *Mycoplasma pneumonia* with galactocerebroside, and cytomegalovirus has crossreactivity with GM2 ganglioside.

Antibody binding to major glycolipid or myelin protein antigens has been shown in both GBS-CIDP and MS. Antibodies may bind to macrophages via their Fc portion, activating phagocytosis and release of inflammatory mediators toward the myelin sheath. An alternative mechanism is through neuromuscular blocking antibodies. An early study of the functional activity of serum IgG antibodies demonstrated a slowing of nerve conduction in marmoset monkeys upon passive transfer of purified IgG from CIDP patients (Heininger et al., 1984). Recently, IgG antibodies that are capable of blocking neuromuscular transmission were identified in CIDP patient serum (Buchwald, Ahangari and Toyka, unpublished observations). This neuromuscular blockade by IgG antibodies has first been observed in GBS and its variant MillerFisher syndrome (Buchwald et al., 1998, 2002).

Human peripheral nerve myelin contains acidic glycosphingolipids such as sulfated glucuronyl paragloboside (SGPG) and sulfated glucuronyl lactosaminyl paragloboside (SGLPG) (Quarles, 1997; Willison and Yuki, 2002). One study found elevated IgM anti-SGPG antibody titers in six of nine patients (67%) with CIDP (Yuki et al., 1996). In earlier studies, antibodies to a variety of glycolipid antigens were described, including LM1, GM1, GD1a (reviewed in Willison and Yuki, 2002). Another candidate antigen is the HNK-1 carbohydrate epitope, which is common to some glycolipids and other cell adhesion molecules. More evidence for the role of GM1 as target has been given when rabbits were immunized with a ganglioside mixture (Yuki et al., 2001): all of them developed high anti-GM1 IgG antibody titers, flaccid limb weakness of acute onset, and a monophasic illness course. Pathological findings for the peripheral nerves showed predominant Wallerian-like degeneration, with neither lymphocytic infiltration nor demyelination. IgG was deposited on the axons of the anterior roots, and GM1 was proved to be present on the axons of peripheral nerves. Sensitization with purified GM1 also induced axonal neuropathy, indicating that GM1 was the immunogen in the mixture and explaining the association of AMAN with anti-GM1 reactivity.

EAN can be induced by immunization of an animal with myelin proteins such as P2 basic protein, P₀ glycoprotein, and peripheral myelin protein 22 (PMP22) (see review in Gold et al., 2005). Gabriel et al (2000) investigated whether PMP22 may be important in inducing human inflammatory neuropathy. The sera of patients with GBS, CIDP, other neuropathies (ONP), and normal controls were evaluated for IgM and IgG antibodies against PMP22. Antibodies were detected in 52%

of patients with GBS, 35% with CIDP, and 3% with ONP; no antibodies were detected in normal controls (Gabriel et al., 2000). Furthermore, Ritz et al (Ritz et al., 2000) reported PMP22 antibodies in three of six (50%) CIDP patients. In contrast, Kwa et al. (2001) reported the absence of these antibodies in sera from 24 patients with CIDP. The discrepancy among the results of these studies may be due to differences in the PMP22 antigen used to test the sera. When linear peptide epitopes of PMP22 and purified PMP22 protein from overexpression in *E. coli* were used, a higher percentage of patient sera showed reactivity. However, when PMP22 protein was expressed in mammalian cells under native conditions, the sera failed to show any reactivity.

In any chronic autoimmune inflammatory condition, several antigens may be involved via epitope spreading (Lehmann et al., 1992), making it difficult to identify the culprit antigen in an individual patient. Moreover, antibodies display a variety of affinities and avidities and some may activate the complement cascade while others may not (Janeway et al., 2001). Therefore, it is not easy to define the pathogenic role of individual antigen binding specificities. Given the heterogeneity of GBS and CIDP, it is likely that different antibodies are sequentially or even collectively involved in the pathogenesis of this disease.

Recent evidence demonstrates that antibodies against myelin protein zero (P_0), a major structural protein of myelin, may play a role in CIDP (Yan et al., 2001). There is indirect evidence that P_0 may have immunologic relevance. In an experimental study of heterozygous P_0 knockout mice, an animal model of Charcot-Marie-Tooth disease, Schmid et al., 2000 showed that (1) myelin degeneration and impairment in nerve conduction were attenuated when the immune system was impaired, and (2) T cells isolated from these mutant mice demonstrated enhanced reactivity to myelin proteins such as P_0 and P2. P_0 , an adhesive cell-surface molecule of the Ig superfamily and the most abundant protein of myelin on the peripheral nerves, has multiple functions in the development and maintenance of myelin (Martini et al., 1995). An increase in macrophages with a subsequent increase in T cells was observed within the nerves of heterozygous P_0 knockout mice. It was hypothesized that a reduction in P_0 could result in an instability of myelin, which then could lead to an attraction of macrophages and a macrophage-mediated attraction of T lymphocytes because these were not tolerized due to lack of myelin protein P_0 in thymus (Visan et al., 2004). Activation of autoimmune T cells by antigen-presenting macrophages could lead to cellular and humoral immune reactions, which ultimately could result in demyelination (Schmid et al., 2000).

Yan et al., 2001 studied the sera of 21 CIDP patients for antimyelin activity using immunofluorescence and for binding to myelin proteins using Western blot analysis. Results showed that the sera of six patients (29%) contained anti- P_0 IgG antibodies, and four of these caused conduction block and demyelination when injected intraneurally into experimental animals. These results suggest that P_0 is an autoantigen in

some patients with CIDP. More work is needed to ultimately define the precise nature of circulating antibodies and their pathogenic role in CIDP.

Summary

There are similarities in the importance of axonal damage in immune neuropathies and MS. Probably in both cases destructive immune responses are involved, presumably by a direct inflammatory assault. They can be counteracted by endogenous survival factors. As yet only some of them have been identified, mostly belonging to the group of neurotrophins or neurotrophic factors. Their therapeutic application is limited because of their absorption in peripheral tissues such as liver, ultimately preventing them from access to the target organ. With the further progress in molecular and cellular gene therapy we may be able to overcome these obstacles. Currently available immune therapies such as plasmapheresis and intravenous immunoglobulins probably limit the damage by reducing the primary inflammatory assault, or by reducing titers of or neutralizing pathogenic autoantibodies.

Review Questions/Problems

- 1. Describe clinical differences between GBS and CIDP.**
- 2. Briefly summarize the different experimental neuritis models in relation to the human diseases.**
- 3. Describe the key immunological factors contributing to axonal damage in GBS and CIDP.**
- 4. Which factors contribute to chronification of the autoimmune inflammation?**
- 5. Which potentially pathogenic humoral elements in CIDP patients have been identified?**
- 6. Which of the following myelin proteins is not involved in experimental neuritis?**
 - a. MAG
 - b. P2 Protein
 - c. P_0 Protein
 - d. MOG
 - e. PMP22
- 7. Which neurotrophic cytokine has been identified as lesion factor in the PNS?**
 - a. NGF
 - b. LIF
 - c. NT-3
 - d. CNTF
 - e. GMCSF

8. Which is the correct explanation for “onion bulb” formation in CIDP?

- a. Macrophages phagocytose myelin debris
- b. Abundant T-cell apoptosis
- c. Repetitive De- and Remyelination with Schwann cell proliferation
- d. Nitric oxide release
- e. Genetic myelin deficiency

9. Which of the following infectious agents is linked to axonal damage and GBS?

- a. *C.jejuni* lior O4
- b. *Neisseria meningitidis*
- c. *Listeria monocytogenes*
- d. *Proteus mirabilis*
- e. *C.jejuni* serotype Penner 19

10. The influence of the immune system on disease progression in genetic myelin disorders.

- a. Has been excluded
- b. Has been clearly shown in experimental models
- c. Has immediate therapeutic implications
- d. Is merely speculative
- e. Has been confirmed only in the Lewis rat

Guillain-Barré Syndrome

Helmar C. Lehmann and Kazim A. Sheikh

Keywords Acute flaccid paralysis; Anti-ganglioside antibodies; *Campylobacter jejuni*; Experimental allergic/autoimmune neuritis (EAN); Gangliosides; Immune neuropathies; Molecular mimicry; T-cells

20.1. Introduction

The term Guillain-Barré syndrome (GBS) is used to denote a group of clinically and pathophysiologically heterogeneous disorders of peripheral nerves that are characterized by acute onset, monophasic course, and potential for substantial recovery, which is expedited by two immunomodulatory therapies. After the near-eradication of polio, GBS is the commonest cause of acute flaccid paralysis worldwide. Current evidence supports the concept that GBS is likely of autoimmune origin. Postinfectious molecular mimicry (autoimmunity) is the currently favored dominant theme in the pathogenesis of GBS. This concept implies antigens shared between the infectious agents and peripheral nerves so that an infection results in an immune response to these crossreactive antigens carried by the organism. The immune response triggered by infection then mediates injury to the peripheral nerves. The results from both clinical and experimental studies on some forms of GBS support this concept. This chapter outlines clinical and pathophysiological features of major variants of GBS and highlights the evidence that supports the hypothesis of postinfectious molecular mimicry in this group of disorders.

20.1.1. Historical Background

The history of GBS is inseparably linked to the seminal paper of Georges Guillain (1876–1961), Jean-Alexandre Barré (1880–1967), and André Strohl (1887–1977) (Guillain et al., 1916). During the weekly meeting of the “*Société médicale des hôpitaux de Paris*” in 1916, they presented the case history of two soldiers of the VI French army, who developed flaccid sensorimotor paralysis. Both patients, without any history of preceding infection, recovered completely after a few weeks. Guillain, Barré, and Strohl were

the first to describe elevated spinal fluid protein without cells “*la dissociation cytoalbuminique*.”

The presentation of Guillain, Barré, and Strohl was not the first clinical description of the disease. Half a century earlier in 1859, Jean Baptiste Octave Landry (1826–1865) described the case of an 43-year-old man who developed an acute ascending paralysis and died within a few days (Landry, 1859). Landry noted a preceding pulmonary infection in his patient. He brought attention to a disease, which he called “*paralysie ascendante aigue*” by further reviewing four of his own and five other cases in the contemporary literature. In contrast to the description of Guillain and Barré, two patients of Landry’s case series died from the disease. Therefore Landry’s acute ascending paralysis had been associated with poor prognosis, whereas Guillain-Barré syndrome was considered to have a mild clinical course with almost complete recovery. Landry noticed preceding infections in two of his cases. Autopsy of his two cases did not show any pathological changes in the central nervous system and this led him to conclude that this disease affects peripheral nerves. In the same year Adolph Kussmaul (1822–1902) (Kussmaul, 1859) reported two cases of a deadly ascending paraplegia. Like Landry, he did not find toxic or anatomical explanation on autopsy. The affection of the peripheral nerve as underlying cause for the disease, was first documented in 1864 when L. Duménil described a case of “*paralysie ascendante aigue*,” in which he found atrophy of peripheral nerve roots in autopsy material (reviewed in Schott, 1982).

It is noteworthy that Landry’s ascending paralysis was a purely clinical diagnosis. It is likely that the early descriptions of Landry and others cover a range of different entities, including atypical forms of polio and infectious neuropathies. Therefore, the application of the lumbar puncture technique by Guillain, Barré, and Strohl was a landmark for classifying and diagnosis of the disease, since it helped to distinguish it from other entities. In 1927 the term Guillain-Barré syndrome was introduced for the first time and become the preferred eponym thereafter (Draganescou and Claudian, 1927). The name of Strohl, who was a medical student in 1916, disappeared unfairly from the original work, although he contributed

substantially by his electrophysiological examinations of the two patients.

A fundamental step towards an understanding of the pathogenesis of GBS was made by observations of inflammatory infiltrates and demyelination in peripheral nerves. These pathological studies on autopsy material led to the assumption that GBS was a single pathophysiological entity synonymous with acute inflammatory demyelinating polyradiculoneuropathy (AIDP) (Haymaker and Kernohan, 1949; Asbury et al., 1969). At the same time Waksman and Adams described the induction of an allergic neuritis in rabbits by immunization with peripheral nervous tissue (Waksman and Adams, 1955). Subsequently this model of an experimental allergic/autoimmune neuritis (EAN) was further expanded to other species, and was used as an *in vivo* model for GBS.

The Fisher syndrome (FS) is named after Charles Miller Fisher, a Canadian neurologist. In 1956, Miller Fisher described three patients with acute external ophthalmoplegia, absent tendon reflexes, and ataxia, who recovered spontaneously (Fisher, 1956). Some cases start as FS but subsequently develop weakness. Finally, work over last two decades indicates that some forms of GBS lack features of demyelination and have pathophysiology that is consistent with axonal injury; these cases are termed axonal GBS.

20.1.2. Classification of GBS Variants

Clinical features and/or electrodiagnostic examination provide a framework for classifying GBS into different variants. GBS can be broadly divided into major and minor variants. The major variants typically have muscle weakness or motor neuropathy as the dominant manifestation; they are further divided into demyelinating and axonal variants on the basis of the predominant pathophysiologic process of nerve fiber injury as determined by electrodiagnostic testing, namely, primary demyelination or primary axonal degeneration. Axonal variants are further subclassified according to the fiber type affected. Minor variants are classified based on the constellation of clinical symptoms and not by electrodiagnostic findings. The constellation of symptoms in minor variants is taken to imply regional localization of the pathophysiologic process. On the basis of this schema a simple classification of GBS is proposed in Table 20.1.

The demyelinating form of the disease is termed acute inflammatory demyelinating polyneuropathy (AIDP). Two axonal forms of GBS (Feasby et al., 1986; Yuki et al., 1990; McKhann et al., 1993), however, are now widely recognized on the basis of nerve fiber type affected: acute motor axonal neuropathy (AMAN), the more common form of axonal GBS, is distinguished by nearly pure motor axonal injury; the less common variant is acute motor-sensory axonal neuropathy (AMSAN), characterized by degeneration of both motor and sensory axons. It has been postulated that AMAN and AMSAN represent a pathologic spectrum and that AMSAN actually represents a more severe form of AMAN (Griffin

TABLE 20.1. Classification of GBS.

Sensory ataxic variant
Acute idiopathic autonomic neuropathy

et al., 1996a). Fisher syndrome (FS) is a minor GBS variant characterized by gait disturbance (ataxia), areflexia, and ophthalmoplegia. Other rarer forms without significant motor weakness that may be included under the term GBS include a predominantly sensory variant and acute idiopathic autonomic neuropathy or acute pandysautonomia.

20.1.3. Epidemiology

The incidence of GBS, 1–1.5 per 100,000 (Rees et al., 1998) is surprisingly similar throughout the world despite different infection rates in various geographical regions. Men are slightly more affected than women (Hughes and Cornblath, 2005) and incidence increases with age (Bogliun and Beghi, 2004). Demyelinating forms of the disease are most prevalent in the United States, Europe (Guillain-Barré syndrome variants in Emilia-Romagna, 1998; Hadden et al., 1998a), and most of the developed world, accounting for over 90% of patients. Compared to western world, the incidence of axonal forms of GBS is higher in northern China, Japan, Mexico and other developing countries but are also, less frequently, seen in northern America and Europe (McKhann et al., 1993; Ogawara et al., 2000; Ramos-Alvarez et al., 1969). Notably, in northern China there is a clear seasonal pattern, with peak incidence in summer months, and a predilection of disease in children and villages (McKhann et al., 1991, 1993). The Fisher variant probably represents 5% of cases of GBS and has a similar incidence world-wide.

20.1.4. Clinical Features

The diagnosis of GBS is primarily clinical. In the AIDP variant the majority of cases have some sensory symptoms or paresthesias at the onset of the disease; however, abnormalities on sensory examination are less frequent. Pain, particularly low back, buttock, or thigh pain, is an early symptom in approximately 50% of patients. Subsequently the clinical picture is dominated by weakness often progressing to paralysis. Muscle weakness may begin in the lower limbs and ascend upwards, characteristically involving both proximal and distal muscles. Respiratory muscles can be involved in up to one-third of the hospitalized patients. Complete or partial loss of reflexes is seen in almost all patients. Cranial nerve involvement is seen

in two thirds of cases, most commonly causing facial weakness and difficulties of eye closure, ophthalmoplegia, difficulty swallowing or altered taste. Autonomic manifestations include reduced sinus arrhythmia, sinus tachycardia, arrhythmias, labile blood pressure, orthostatic hypotension, abnormal sweating, and pupillary abnormalities. Respiratory and bulbar weakness and autonomic instability are the major cause of morbidity and mortality in GBS.

Clinically, it is difficult to distinguish between axonal and demyelinating forms of GBS. Electrodiagnostic testing is essential to differentiate these variants. AMAN has exclusively motor findings, with weakness typically beginning in the legs, but in some individuals affecting arms or cranial muscles initially (McKhann et al., 1993). Tendon reflexes are preserved until weakness is severe enough to preclude phasic muscle contraction. This probably reflects sparing of muscle afferent fibers. The incidence of dysautonomia has not been systematically examined in axonal cases but it was seen in a small proportion of cases.

Minor variants without significant motor weakness include FS characterized by ataxia, areflexia, and internal and external ophthalmoplegia. Other rarer forms of the disease without significant muscle weakness include a pure sensory variant and acute autonomic neuropathy.

Differential diagnoses include structural lesions, such as myelopathy and infections including HIV, Lyme disease, CMV, rarely paralytic rabies (Sheikh et al., 2005), and, in endemic areas, polio. In children botulism should be considered. Toxic and metabolic conditions such as tick bite and porphyria can also mimic GBS. In the intensive care setting, critical illness neuropathy and quadriplegic myopathy may be clinically indistinguishable from GBS.

20.1.4.1. Investigations

The main aim of the investigations is to exclude other conditions that can mimic GBS and to confirm the diagnosis. Electrodiagnostic testing is the most critical investigation in the evaluation of patients with GBS; it can potentially provide support for the clinical diagnosis and useful prognostic information. Nerve conduction studies (NCS) are abnormal to some extent in most patients with GBS, but normal studies in the first week do not exclude this diagnosis. Gordon and Wilbourn reported the changes in NCS seen in the first week (Gordon and Wilbourn, 2001). Changes in F wave latencies are probably the most common abnormality early in disease. In AIDP, typical electrophysiological features of demyelination such as slow motor conduction velocities, prolonged distal motor latencies, and partial motor conduction block may not be present until the second or third week. Reduced or absent sensory nerve action potentials (SNAPs) and slowing of sensory conduction velocity are common. In contrast to AIDP, conduction times like distal motor latencies and motor conduction velocities are relatively preserved in the axonal forms, but reduced compound motor action potential (CMAP) amplitudes are characteristic. Inexcitable motor nerves can be seen in more severe cases and in patients

TABLE 20.2. Anti-glycolipid antibodies in different GBS variants.

Variants	Anti-glycolipid antibody
Fisher syndrome	GQ1b/GT1a
AMAN	GD1a, GM1, GM1b, GalNAc-GD1a
AIDP	GM1, Asialo-GM1, GD1b, GM2, LM1, GD2, GalC, Forssman antigen
Sensory ataxic variants	GD1b and structurally related gangliosides

with the AMSAN variant. Sensory conduction studies are usually normal in AMAN, but SNAPs are decreased or absent in the AMSAN variant. Examination of cerebrospinal fluid (CSF) is most useful in excluding other differential diagnoses, particularly infections. Typically, CSF protein is increased in 80–90% of GBS cases without significant pleocytosis. A mild increase in mononuclear cells can be seen in up to 10% of patients. Significant pleocytosis raises the possibility of infection such as Lyme disease or HIV. Serological studies for anti-ganglioside antibodies can be considered for the diagnosis in incomplete forms and unusual variants of GBS, particularly when nerve conduction studies and CSF are normal. The role of anti-ganglioside serology in routine diagnosis and clinical decision-making remains to be established. Table 20.2 summarizes the common anti-glycolipid antibodies reported in association with various forms of GBS.

20.1.4.2. Clinical Course

GBS may progress up to 4 weeks with a nadir being reached within 2–3 weeks in a majority of patients. Recovery usually begins within 2–4 weeks of this nadir, but can be delayed for several months. About one-half of patients become chair- or bed-bound, one-third require intensive care admission, and one-quarter mechanical ventilation (Winer et al., 1988; Rees et al., 1998; Hughes and Cornblath, 2005). Functional recovery is a rule and occurs in a majority of patients over 6–12 months; however 20–30% of patients are left with significant disability and about 10% require assistance with walking. The mortality rate ranges between 3 and 8%, and most deaths are attributed to cardiac arrest due to autonomic disturbance, respiratory failure or infection, or pulmonary embolism.

20.1.4.3. Prognosis

The extent and location of axonal injury are the two most important determinants of prognosis after an episode of GBS. Residual disability almost always indicates axonal degeneration. Axon regeneration is required for restoration of function. In GBS, there is characteristically significant pathology in spinal roots and proximal nerves and as peripheral axon regeneration advances at a rate of approximately 1 in./month, recovery is slow and often incomplete. Although peripheral axons have the capacity to regenerate, experimental evidence indicates that: (a) the efficiency of axonal regeneration decreases over time after injury (Fu and Gordon, 1995a); (b) the denervated distal segment of peripheral nerves can optimally support axon regeneration only for a limited time (Fu and Gordon, 1995b);

and (c) the efficiency of reinnervation of original pathways and targets (pathfinding) decreases with advanced age (Le et al., 2001). Poor recovery after axonal GBS is not always the rule; exceptions include children with electrical features of acute denervation, cases with distal axonal degeneration where regeneration is needed over only a short distance, or patients with reversible axonal conduction failure. Poor prognostic factors include advanced age, ventilator dependence, preceding gastrointestinal infection, rapid progression from onset to nadir, severe motor involvement, and electrodiagnostic evidence of extensive axonal injury.

20.1.5. Pathology

Pathology of demyelinating and axonal forms presented below is well established. Pathological changes in minor variants of GBS are not well-characterized.

AIDP: The pathological changes in AIDP have been extensively characterized in postmortem studies. The most prominent feature in AIDP is marked segmental demyelination, which can be found throughout the length of all peripheral nerves including the mixed spinal roots and even the distal terminal nerves (Hall et al., 1992; Massaro et al., 1998). In areas of severe demyelination, signs of secondary axonal degeneration can be observed. Another pathological hallmark is the presence of inflammatory infiltrates, especially in the spinal roots and proximal nerves, which contain T-lymphocytes and macrophages (Asbury et al., 1969; Prineas, 1981). Macrophage-mediated myelin stripping (ingestion/breakdown) is characteristic. Lymphocytic infiltration can be minimal, however, sometimes it may not occur; moreover, localization may differ markedly (Cornblath et al., 1990; Honavar et al., 1991). In a recent postmortem study, inflammatory infiltrates have also been detected in the spinal cord of GBS patients, indicating that there may be subclinical inflammation of CNS structures (Muller et al., 2003). In some cases of AIDP there is breakdown of blood-nerve barrier with deposition of activated complement products on Schwann cells, suggesting a role for antibody-mediated immune injury (Hafer-Macko et al., 1996b). These pathological observations implicate T-cells or autoimmune antibodies in inducing peripheral nerve demyelination in individual cases. Further, T-cell and antibody-mediated immune injury can predominate or act synergistically in an individual case.

Axonal variants: Unlike AIDP, axonal variants of GBS show primary axonal injury without substantial T-cell inflammation or demyelination (Griffin et al., 1995, 1996a). In AMAN, axonal degeneration predominantly involves the motor axons, whereas in AMSAN sensory axons are also involved. It has been postulated that AMAN and AMSAN represent a pathologic spectrum and that AMSAN actually represents a more severe form of AMAN.

In AMAN, deposition of IgG and complement can be detected on the nodal and internodal axolemma (Hafer-Macko et al., 1996a). Macrophages are closely associated with the axons at the nodes and these cells then extend into internodal

regions where they surround axons, without disturbing/disrupting the overlying myelin, eventually leading to axon degeneration (Griffin et al., 1995, 1996a). The findings of IgG deposition on axolemma and periaxonal location of macrophages strongly imply that the potential target antigen(s) are expressed on the surface of (motor) axons. Current pathogenetic concepts assume that antibody binding to motor axolemma leads to activation of complement, recruitment of macrophages instead of macrophages, and subsequent degeneration of axons.

Pathologic examination of early cases has shown that at the onset the pathological alterations in AMAN are mainly restricted to the nodes of Ranvier of motor fibers in the ventral roots (Griffin et al., 1996b). In these cases nerve fibers still appear normal except that the nodal gap is lengthened. It is believed that this nodal lengthening is sufficient to cause failure of transmission of nerve impulses and profound clinical weakness. Motor nerve terminals are another site susceptible to injury in AMAN, as indicated by degeneration of intramuscular nerves on muscle biopsy (Ho et al., 1997). These observations suggest that nodes of Ranvier and motor nerve terminals are two sites that are susceptible to injury in AMAN.

In summary, the pathological and immunopathological findings in AMAN suggest that antibody-mediated injury directed against axonal antigens plays a prominent role in the pathogenesis of this disorder.

20.1.6. Treatment

- (a) *Supportive care* is the mainstay of medical management in patients with GBS, despite the availability of immunomodulating therapies like plasma exchange and (PE) and intravenous immunoglobulins (IVIg). All patients with GBS should be admitted to a hospital with an ICU experienced in GBS care. The major risks are complications arising from weakness of respiratory and bulbar muscles and autonomic instability. The principles of supportive management include respiratory support in patients with respiratory failure, monitoring and management of dysautonomia, measures to prevent nosocomial infections and complications of immobility, and pain management.
- (b) *Immunomodulatory therapies* controlled clinical trials have shown that IVIg and PE are beneficial immunomodulatory treatments in GBS in populations where AIDP is the predominant form of the disease (reviewed in Raphael et al., 2002; Hughes et al., 2004; Hughes et al., 2001). These trials indicate that treatment with PE or IVIg should be considered for all nonambulatory adult patients with AIDP. IVIg is now the first line of treatment for most patients because it can be administered easily and patient acceptance is high. Immunomodulatory treatments should begin as soon as possible after the onset of symptoms to obtain maximal benefit and limit the extent of nerve injury. There are no controlled studies of immunomodulatory therapy in the FS and primary axonal variants of GBS, but anecdotal reports indicate that

FIGURE 20.1. Hypothetical scheme of the immune response in acute inflammatory demyelinating polyradiculoneuropathy (AIDP): Inflammatory cells migrate from the systemic immune compartment through the damaged blood-nerve barrier into the endoneurium. Inflammatory infiltrates, which contain T-lymphocytes and macrophages cause marked segmental demyelination and secondary axonal degeneration (B: B-cell; T: T-cell; MΦ: Macrophage).

both PE and IVIg are beneficial. There is no evidence that corticosteroids are beneficial for treatment of GBS (Hughes and van der Meche, 2000). The current data indicate that the use of multiple immunomodulatory treatment modalities (PE followed by IVIg) is not superior to single therapy (PE or IVIg) for the treatment of GBS.

The precise mechanism(s) of action of PE and IVIg in GBS remain uncertain. PE removes a number of potentially pathogenic circulating factors including autoimmune antibodies, cytokines and complement, and can alter lymphocyte activation (Lehmann et al., 2006). IVIg is proposed to neutralize and inhibit production of autoantibodies, suppress antibody dependent cellular cytotoxicity, decrease natural killer cell function, down-regulate proinflammatory cytokines, and interfere with complement activation (Dalakas, 2002, 2004). It is also proposed that IVIg induces increased catabolism of immunoglobulins including autoantibodies by saturating FcRn transport receptors (Yu and Lennon, 1999).

20.2. Pathogenesis of GBS Variants

This section describes the current concepts and hypotheses about the pathogenesis of different forms of GBS. Because of pathological findings demonstrating the presence of T-cell inflammation in AIDP nerves, most of the research in this disorder has focused on T-cell-orchestrated demyelination.

Experimental allergic/autoimmune neuritis (EAN) is a prototypic model of this disease that has provided useful insights into the pathogenesis of AIDP, despite concern about the relevance of this model to human disease because antigen(s) specificity of lymphocyte responses in AIDP is not well defined.

Significant progress has been made in our understanding of the pathogenesis of AMAN and FS variants of GBS. This progress is largely driven by identification of specific anti-ganglioside antibodies in AMAN and FS, which has focused research in this area on antibody-mediated pathophysiologic effects on nerve fibres. Clinical observation that *Campylobacter jejuni* infection commonly precedes GBS and demonstration of ganglioside-like antigens on this infectious organism has provided strong support to the hypothesis of post-infectious molecular mimicry as the predominant pathophysiologic mechanism in AMAN and FS variants of GBS.

The abnormalities of cellular immunity in patients with AIDP and its experimental animal model EAN are discussed to highlight pathogenetic events involved in cell-mediated demyelination. This is contrasted with role of humoral immunity in pathogenesis of AMAN by reviewing pathophysiologic effects of anti-ganglioside antibodies on corresponding antigens (gangliosides) expressed by axons. FS is also included in the discussion because pathophysiologic effects of specific anti-ganglioside antibodies associated with this disorder have also been elucidated. Figures 20.1 and 20.2 summarize the immune mechanisms invoked in AIDP and AMAN variants of GBS, respectively.

FIGURE 20.2. Proposed pathogenesis in acute motor axonal neuropathy (AMAN): In AMAN there is primary axonal injury without T-cell inflammation and demyelination. Deposition of autoantibodies and complement on the axolemma is followed by structural axonal injury or alteration of axon conduction. Macrophages within the periaxonal space contribute to the axonal damage (B: B-cell; MΦ: Macrophage, C5b-9: complement factors).

20.2.1. Acute Inflammatory Demyelinating Polyradiculoneuropathy (AIDP)

Most of our understandings about the cellular mechanisms in the pathogenesis of AIDP have been gained by studies of the experimental allergic/autoimmune neuritis (EAN). In particular, the important role of T-cells in the pathogenesis of EAN has paved the way for the development of hypothetical models for human AIDP. EAN can be induced in different species with whole peripheral nerve tissues or neuritogenic epitopes of peripheral nerve proteins P0, P2, and PMP22 (Hughes et al., 1999). A modified model is the adoptive transfer EAN, where specific T-cell lines against P0 or P2 are passively transferred to the animals induce neuropathy. EAN is a monophasic disease; its severity is associated with cell or antigen dosage (Hartung et al., 1996). Depletion of T-cells by thymectomy or antibodies against T-cells can protect against EAN, indicating that disease induction is dependent on the presence of T-cells (Holmdahl et al., 1985). Further, a normal function of T cells (Holmdahl et al., 1985; Hartung et al., 1987; Jung et al., 1992) and the presence of costimulatory molecules B7.1/CD80 or B7.2/CD86 and CTLA4/CD28 (Kiefer et al., 2000; Zhu et al., 2001a, b, 2003) are required for inducing and supporting EAN, which emphasizes the important role of T-cells as mediators for experimental neuritis.

T cell activation in EAN is accompanied by expression of inflammatory cytokines such as IFN- γ , TNF- α , TNF- β , IL-6 and IL-12 (Zhu et al., 1994, 1997). In sera of GBS, inflammatory cytokines detected include IFN- γ , TNF- α and IL-2, which are increased in patients and partially correlate with disease

activity (Taylor and Hughes, 1989; Hartung and Toyka, 1990; Hartung et al., 1991; Exley et al., 1994; Creange et al., 1996). In contrast, levels of TGF- β 1, a pleiotrophic cytokine, are lower in GBS patients than in controls (Creange et al., 1998).

Systemic immune activation in AIDP is reflected by an increased number of activated T-cells circulating in the peripheral blood during the early disease course (Taylor and Hughes, 1989; Hartung and Toyka, 1990). Many studies to identify the putative antigen of a specific T cell response in AIDP provided conflicting results. Some studies postulated that peptides from P0 and P2 might be the epitope of specific T-cell lines in GBS, but most of them failed to obtain disease specific T-cell responses against neural antigens. The CD4/CD8 ratios of T-cell populations detected in the peripheral nerves in AIDP closely resemble those in the peripheral blood. Of those, $\alpha\beta$ T-cells constitutes most of the nerve infiltrates (Cornblath et al., 1990). The usage of V β 15 T-cell receptor gene suggest the specific T-cell activation by a common antigen or superantigen (Khalili-Shirazi et al., 1997).

In the normal human immune repertoire there are far fewer T-cells that express the $\gamma\delta$ T-cell receptors than those expressing $\alpha\beta$ T-cell receptors. Unlike $\alpha\beta$ T-cells they do not recognise antigenic peptides in the context of MHC molecules and these cells are mainly localised in epithelial barrier tissue. Interestingly, $\gamma\delta$ T-cells were isolated from sural nerve biopsies of GBS patients (Winer et al., 2002). A specific role of those $\gamma\delta$ T-cells has been postulated, as they may recognize non-protein antigens. Therefore, they could initiate an immune response to potential carbohydrate and glycolipid antigens (Winer et al., 2002). The proliferation of $\gamma\delta$ T-cells in response to *C. jejuni*

lysates has been shown. Nonetheless, $\alpha\beta$ T-cells or stimulatory cytokines such as IL2 are required for expansion of $\gamma\delta$ T-cells (Van Rhijn et al., 2003). These studies suggest that T-cell subtypes with specificity for peptide and glycolipid antigens can invade the nerves in AIDP.

A crucial step during the process of inflammation is the migration of activated T-cells from the systemic immune compartment to the sites of inflammation. Like the CNS, the peripheral nerve represents an immunologically privileged environment, protected by an intact blood-nerve barrier. In EAN, the breakdown of the blood-nerve barrier is one of the earliest pathological changes that can be found. The upregulation of specific endothelium-binding molecules on T-cells and their specific ligands on vascular endothelium precedes the migration of T-cells through the blood-nerve barrier. E-Selectins binding sialyl Lewis antigens (Hartung et al., 2002) and VCAM-1/ ICAM-1, are both upregulated in GBS and EAN (Enders et al., 1998; Creange et al., 2001). EAN can be partially inhibited by blocking VCAM-1 or its ligand VLA-4/ $\alpha 4$ - $\beta 1$ integrin (Enders et al., 1998). E-selectins are released into the blood and can be found in elevated levels in GBS patients. Chemokines, which exert chemotactic effects on leucocytes by binding to their specific receptor, contribute to the migration of inflammatory cells (Baggio-olini, 1998; Campbell et al., 1998). The differential expression of chemokines and their receptors has been studied in detail in sural nerves of patients with AIDP (Kieseier et al., 2002a). Of those, specific upregulation of CCR-2 and CCR-4 were detected in invading T-cells, whereas endothelial cells expressing the chemokine IP-10 were identified (Kieseier et al., 2002b).

Matrix metalloproteinases (MMPs), a heterogeneous group of zinc-dependent endopeptidases, are assumed to contribute to the structural breakdown of the blood-brain barrier, extravasation of leukocytes, and direct demyelination. In EAN, MMP9 and MMP7 are upregulated during early disease course and correlate with disease severity (Kieseier et al., 1998). Further, the administration of MMP inhibitors may attenuate the disease (Redford et al., 1997b). Human CSF samples from patients with GBS show increased gelatinase B activity (Creange et al., 1999). In sural nerve biopsies from GBS patients, augmented proteolytic activity for gelatinase B as well as increased mRNA expression for gelatinase B and matrilysin were detected (Kieseier et al., 1998). MMPs in the inflamed PNS appear not only to promote inflammation, but may also play a role in nerve repair. For example, in EAN, matrilysin remained upregulated throughout the clinical recovery phase, implicating a possible role of this metalloproteinase in restoring the integrity of the PNS (Hughes et al., 1998).

Because macrophages represent the major cell population in infiltrates of affected nerves, they are considered to be key mediators of injury to myelin, Schwann cells, and axons. This hypothesis is reinforced by experimental studies, where depletion of macrophages prevents the development of EAN. Although endoneurial macrophages are present in

low frequency in the normal peripheral nerve, most of them migrate through the blood-nerve barrier during the process of inflammation (Hartung et al., 2002). Macrophages may exert their pathological effects by release of inflammatory mediators. Of those, MMPs, TNF α , nitric oxide, and others have been postulated to mediate neurotoxicity (Redford et al., 1997a, b; Hartung et al., 2002). Besides direct harmful effects to nerve fibres, macrophages also perpetuate the inflammatory process by antigen-presenting to T-cells. It is assumed that macrophages also attack Schwann cells in AIDP (Prineas, 1981; Hartung et al., 1996) by antibody-mediated cytotoxicity and activation of complement (Hafer-Macko et al., 1996a, b). Another mechanism for Schwann cell injury/demyelination is via CD8+ T-cells, which are cytolytic T-cells that mediate cytotoxic effects by release of perforin and granzymes. Recently, CD8+ T-cells have been detected in postmortem tissue of GBS patients with prolonged disease course. These results point to an additional direct role of T cell-mediated cytotoxicity in AIDP (Van Rhijn et al., 2003).

There is a growing interest in the role of humoral factor-induced demyelination in AIDP. In demyelinating cases from China, complement activation markers were found on the abaxonal Schwann cell surface. They were associated with vesicular demyelination (Hafer-Macko et al., 1996b) and closely resemble the experimental nerve fiber demyelination induced by anti-galactocerebroside (a glycosphingolipid enriched in myelin) antibody in the presence of complement (Saida et al., 1979a). It is likely that in these cases, the antibody and complement are directly involved in targeting the Schwann cell and myelin, and the role of T-cells may be to open the blood-nerve barrier (Spies et al., 1995a, b). This concept is supported by the observations that disease severity in models of adoptive transfer-EAN is enhanced by transferring antibodies that recognise myelin or Schwann cell epitopes (Hahn et al., 1993; Spies et al., 1995a). Several clinical and experimental observations also support a role for antibody-mediated mechanisms, including the response to plasmapheresis, the presence of anti-myelin and anti-glycoconjugate antibodies (reviewed in (Hughes et al., 1999), and the ability of AIDP sera to induce demyelination after intraneural injection (Saida et al., 1982). Anti-ganglioside antibodies of various specificities have been described in AIDP but their pathogenic role is not accepted because of lack of experimental models demonstrating their demyelinating activity. Antibodies against GM1, GD1b, asialo-GM1, the Gal($\beta 1$ -3)GalNAc epitope, GM2, LM2, and GT1b (reviewed in (Hughes et al., 1999; Willison and Yuki, 2002) have been described, but antibodies to these gangliosides are not routinely detected.

Although substantial progress has been made in our understanding of the cellular mechanisms that might underlie nerve fibre injury in AIDP, however, definition of target antigens and how the undesirable processes of inflammation, myelin degradation, and subsequent axonal damage are initiated remain unclear.

20.2.2. Acute Motor Axonal Neuropathy (AMAN)

Unlike for AIDP there are almost no clinical or experimental data that have systematically examined the role of cellular immunity in AMAN. Clinical studies over the last 15 years show that patients with AMAN have specific antibodies against two major gangliosides, GM1 and GD1a, and two minor gangliosides, GalNAc-GD1a and GM1b in the peripheral nerves (Figure 20.3A) (Rees et al., 1995a; Jacobs et al., 1996; Hadden et al., 1998b; Ho et al., 1999; Ogawara et al., 2000; Yuki et al., 1993b; Kusunoki et al., 1994, 1996). Most of the data originates from Japan and northern China, where the AMAN form of the disease and preceding *C. jejuni* infections are frequent. Anti-GM1 antibodies have been reported in up to 50% of Japanese patients with AMAN (Ogawara et al., 2000). Anti-GD1a antibodies are present in up to 60% of patients with AMAN compared to 4%

in AIDP in northern China (Ho et al., 1999). The frequency of anti-GalNAc-GD1a and -GM1b in motor-predominant GBS is about 10–15% (Kusunoki et al., 1994, 1996; Yuki et al., 1999). Anti-ganglioside antibodies in AMAN are mostly IgG isotype and are commonly IgG1 and IgG3 (Willison and Veitch, 1994; Ogino et al., 1995), which are complement-fixing subtypes in humans. These anti-ganglioside antibodies are oligoclonal or polyclonal and can have a broad range of crossreactivity. In AMAN, the differences of antibody specificity in different populations are not well understood. There are some data to suggest differences in immunogenetic repertoire, and geography may affect the specificity and isotype distribution of anti-ganglioside antibodies in various populations (Ogawara et al., 2000; Ang et al., 2001b).

A brief discussion of peripheral nerve gangliosides is necessary for understanding the pathogenetic effects of anti-ganglioside antibodies. Gangliosides, the target antigens of

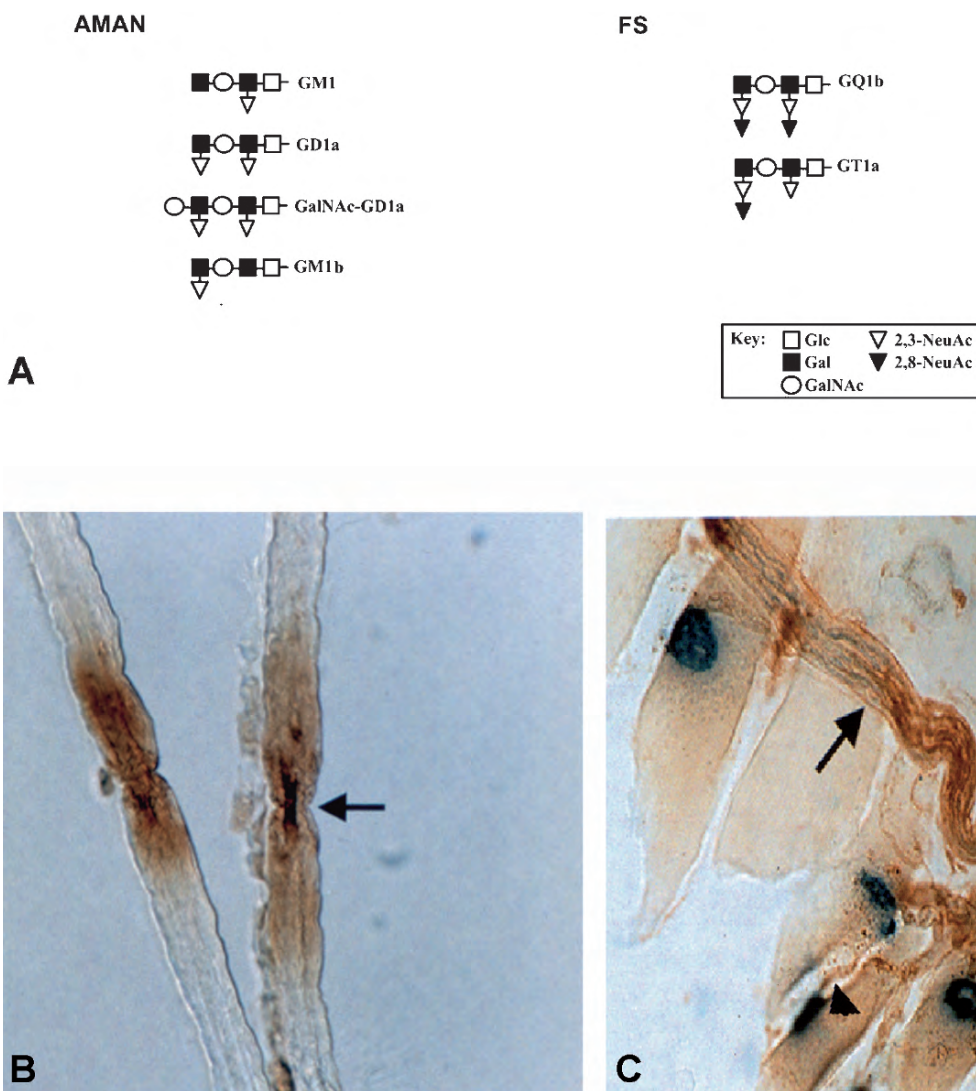

FIGURE 20.3 (A) Schematic diagrams showing the glycan structures of gangliosides implicated as target antigens in AMAN and FS. (B) Teased nerve fibers showing GM1 staining at node of Ranvier (arrow) and paranodal Schwann cells. (C) GM1 is also localized to intramuscular nerve (arrow) and motor nerve terminal (arrowhead); blue staining marks motor end plates (adapted with permission from Sheikh et al., 1999).

anti-ganglioside antibodies, are sialic acid-containing glycolipids enriched in the mammalian nervous system. They contain one or more sialic acids linked to an oligosaccharide chain of variable length and complexity, which is attached to ceramide lipid anchor (Kolter et al., 2002). The ceramide portion of gangliosides anchors them in plasma membranes and glycan moieties are expressed on cellular/axonal surfaces. This organization allows anti-ganglioside antibodies to bind to glycan moieties on cell surfaces. The most abundant gangliosides in the adult mammalian nervous system are GM1, GD1a, GD1b, and GT1b; in peripheral nerves LM1 ganglioside is also enriched, particularly in myelin (Yu and Saito, 1989; Svennerholm et al., 1992, 1994; Ogawa-Goto et al., 1990, 1992). Complex gangliosides are more concentrated in axolemmal fractions; GM1 is enriched in both axons and myelin (Yu and Saito, 1989). Immunolocalization studies indicate that in normal rodents and humans, all complex gangliosides including GM1 and GD1a reside in axons, and GM1 is also found in paranodal Schwann cells, but compact myelin in internodal segments is difficult to stain with anti-ganglioside antibodies or toxins (Ganser et al., 1983; Sheikh et al., 1999; Gong et al., 2002). Minor gangliosides GalNAc-GD1a and GM1b are expressed in peripheral nerves and one study suggests that GalNAc-GD1a may only be expressed by motor neurons and nerve fibers (Ilyas et al., 1988; Yoshino, 1997). In summary, it is important to emphasize that GM1 and GD1a gangliosides are present at the nodes of Ranvier and motor nerve terminals: two sites along the motor nerve fibers reported to be involved in patients with AMAN. Distribution of GM1 gangliosides at nodes of Ranvier and motor nerve terminals is shown as an example in Figure 20.3B-C.

Several anatomical and physiological features make nodes of Ranvier and motor nerve terminals susceptible to antibody-mediated nerve injury: (1) most complex gangliosides are concentrated at the nodes and motor nerve terminals; (2) in myelinated fibers, axonal target antigens are exposed at these sites; (3) sodium and potassium ion channels are clustered at the nodes and disruption of their function can disrupt impulse conduction; (4) structural integrity of the node of Ranvier is critical for nerve fiber conduction; (5) motor nerve terminals are enriched in sodium and calcium channels and disruption of their functions can affect distal impulse conduction or neurotransmitter release at the neuromuscular junctions, respectively. Further, multiple studies indicate that gangliosides are concentrated in microdomains called lipid rafts that are specialized for cell signaling and that modulation of these lipid raft gangliosides can modulate receptor function, including ion channel function.

With this background information, we outline the experimental data that supports the notion that anti-ganglioside antibodies can induce nerve fiber injury in animal models and briefly review the effects of these antibodies on nodes of Ranvier and motor nerve terminals. Two animal models that provide 'proof of concept' that anti-ganglioside antibodies with -GM1 and -GD1a specificities can induce neuropathy.

First, Yuki and colleagues used GM1 ganglioside or *C. jejuni* lipopolysaccharide (LPS) with a mixture of keyhole limpet hemocyanin and complete Freund's adjuvant for repeated immunizations in rabbits to induce high titers of anti-GM1 antibodies, clinical paralysis, and electrophysiological and pathological evidence of motor axon injury (Yuki et al., 2001, 2004). The pathological and immunopathological studies in these animals showed features similar to that of human disease, i.e., deposition of IgG on motor axons and the presence of periaxonal macrophages. Further, analysis of animals shortly after the onset of clinical weakness showed only lengthening of the nodes of Ranvier without morphological features of axon degeneration (Susuki et al., 2003). We took an alternative approach to induce neuropathy in mice with anti-GD1a antibodies. This included generation of monoclonal anti-GD1a antibodies (Lunn et al., 2000) and implantation of antibody-secreting hybridoma in mice (Sheikh et al., 2004). Animals implanted with hybridoma develop high titers of anti-GD1a antibodies and axonal neuropathy in peripheral nerves and motor nerve terminals. Our studies showed that hybridoma implantation in transgenic mice lacking complex gangliosides (including GD1a) did not induce neuropathy despite high circulating levels of antibodies, confirming that gangliosides are indeed the target antigens of anti-ganglioside antibodies in this model (Sheikh et al., 2004).

The pathophysiologic effects of anti-ganglioside antibodies on nodes of Ranvier have been examined both *in vitro* and in animal models. Most of the studies have used anti-GM1 antibodies derived from patients with acute and chronic immune neuropathies or produced experimentally. It has been reported that intraneural injections of sera containing anti-GM1 can induce acute conduction block (Santoro et al., 1992; Uncini et al., 1993). We have recently examined the effects of anti-GD1a and GM1 monoclonal antibodies in an intraneural injection model and found that these antibodies induce conduction block and lengthening of the nodes of Ranvier (David et al., 2005). Takigawa and colleagues examined the effects of anti-GM1 sera on ion channel function at the nodes of Ranvier by using a voltage clamp technique on isolated myelinated fibers. They found that in the presence of complement these antibodies induced irreversible decreases in sodium currents and eventual blockade of the channels (Takigawa et al., 1995, 2000). Nonetheless, other investigators have been unable to reproduce these findings (Harvey et al., 1995; Hirota et al., 1997). Possible explanations include differences in experimental paradigms, including sources of antibodies, and affinity and fine specificity of these antibodies. Overall, these studies support the concept that anti-ganglioside antibodies can alter the nodal architecture and directly modulate ion channel function at the nodes of Ranvier.

The effects of anti-ganglioside antibody-mediated injury on motor nerve terminals have been extensively examined by *in vitro* phrenic nerve-diaphragm preparations. Current

concepts indicate that anti-ganglioside antibodies can exert immunopharmacological effects on motor nerve terminal physiology and that they can also induce complement-dependent cytotoxic injury to motor nerve terminals. We have recently examined the effects of IgG anti-GM1 and -GD1a antibodies on motor nerve terminals by a perfused macro-patch clamp model with Buchwald's group. Our studies indicate that anti-GM1 and -GD1a antibodies depressed the evoked quantal release (Buchwald et al., 2004). This blockade was reversible or partially reversible after washout of these antibodies and did not require complement. Since calcium channels are critical in evoked quantal release, we examined the effects of these antibodies on depolarization-induced calcium influx by calcium imaging. These studies indicate that anti-GM1 and -GD1a antibodies significantly decrease depolarization-induced calcium influx, suggesting that antibody binding to gangliosides in the presynaptic motor terminals alters calcium channel function (B. Buchwald, K. Sheikh, unpublished observations). Work done by others has characterized the complement-dependent pathophysiological effects of anti-GD1a antibodies on motor nerve terminals in *ex vivo* hemidiaphragm preparations (Goodfellow et al., 2005). They showed that dense antibody and complement deposits develop over presynaptic motor axons, accompanied by severe ultrastructural damage and electrophysiological blockade of motor nerve terminal function. This pathophysiological effect, however, required high density expression of GD1a ganglioside (Goodfellow et al., 2005).

In summary, experimental data indicate that active immunization with GM1 ganglioside or *C. jejuni* LPS can reproduce pathophysiological features of AMAN in a rabbit model. Passive transfer with an anti-GD1a monoclonal antibody (by hybridoma implantation) also reproduced axon and motor nerve terminal degeneration in a mouse model. Anti-GM1 and -GD1 antibodies can alter the nodal and motor nerve terminal function and architecture. Tissue and cell culture studies indicate that sodium and calcium ion channel function can be modulated by these antibodies at nodes of Ranvier and presynaptic motor nerve terminals, respectively. These antibodies have both complement-independent immunopharmacologic and complement-dependent cytotoxic effects. The detailed subcellular and molecular effects of these antibodies on motor axons remain to be elucidated. Preferential susceptibility of motor axons to anti-GM1 and -GD1a antibody-mediated injury in AMAN is another fundamental issue that remains unresolved, because biochemical studies indicate that both motor and sensory nerve fibers have similar levels of ganglioside expression (Gong et al., 2002). Despite these and other gaps in our knowledge about the pathogenetic sequence of this disorder, current data support the hypothesis that anti-ganglioside antibodies can induce pathophysiological effects on intact motor nerve fibers.

20.2.3. Fisher Syndrome

Several studies have indicated that anti-GQ1b antibodies are present in more than 80% of the cases with FS (Chiba et al., 1992; Willison et al., 1993; Yuki et al., 1993a). Preceding *C. jejuni* infection is not uncommon in this disease. Anti-GQ1b antibodies in patients with FS can be IgA, IgM, or IgG isotype but the IgG response is most robust and persistent. These IgG antibodies are of complement-fixing isotypes, similar to those in AMAN. Studies indicate that anti-GQ1b antibodies commonly cross-react with a structurally related ganglioside GT1a (Figure 20.3A) (Chiba et al., 1993; Ilyas et al., 1998). Biochemical and immunolocalization studies have mapped the distribution of GQ1b ganglioside in the peripheral nerves: anti-GQ1b antibodies bind to paranodal myelin and nodes of Ranvier, and neuromuscular junctions (NMJs) in extraocular and somatic muscles, and it has been shown that the GQ1b is twice as frequently expressed in the extraocular cranial nerves than in other cranial and somatic peripheral nerves (Chiba et al., 1993, 1997). Pathogenetic studies indicate that anti-GQ1b antibodies bind at the nodes of Ranvier but are unable to induce acute conduction failure (Paparounas et al., 1999). This experimental result has led to the notion that antibody-mediated conduction failure at the levels of the nodes of Ranvier may be less important in the pathogenesis of FS. Because extraocular muscles are paralyzed in FS, anti-GQ1b antibodies do not affect nodal function, and anti-GQ1b antibodies bind to NMJs, experimental approaches have focused on pathophysiological effects of anti-GQ1b antibodies on NMJs to model ophthalmoplegia seen in FS. In this regard phrenic nerve hemi-diaphragm preparations have been used extensively to study the pathological effects of anti-GQ1b antibodies.

Investigators have examined the effects of FS sera, FS IgG, or human anti-GQ1b antibodies on NMJs and showed that these antibodies bind to NMJs, cause massive quantal release of acetylcholine from nerve terminals and eventually block neuromuscular transmission, primarily through pre-synaptic mechanisms. These pathophysiological effects were complement-dependent and resembled the effects of paralytic neurotoxin alpha-latrotoxin (Plomp et al., 1999). Willison and colleagues have shown that these antibodies induce degeneration of preterminal motor axons both by direct cytotoxicity and indirectly through damage to perisynaptic Schwann cells at NMJs (O'Hanlon et al., 2001; Halstead et al., 2004, 2005). In contrast, Buchwald et al. (Buchwald et al., 1995, 1998, 2001), reported complement-independent immunopharmacological effects of IgG fractions from both GQ1b-positive and -negative FS on NMJs. They showed that these IgG fractions blocked release of evoked acetylcholine and depressed the amplitude of postsynaptic potentials, implicating both a pre- and postsynaptic blocking effect. This effect was reversible. That the antibody-mediated pathophysiological effects at NMJs may be relevant

to clinical disease is supported by an electrophysiological study suggesting that this site is affected in some cases with FS (Uncini and Lugaresi, 1999). There are no existing animal models of FS.

20.3. Molecular Mimicry Hypothesis

In this section we consider microbial agents that commonly cause infections preceding GBS and are reported to carry antigens crossreactive with peripheral nerves. The demonstration of peripheral nerve-crossreactive epitopes in these microbes is the basis for the hypothesis of post-infectious molecular mimicry in GBS. In this regard *Campylobacter jejuni* (*C. jejuni*) is the most well characterized, and stringent data exist that demonstrate the presence of ganglioside-like antigens in these organisms. Recent studies have also implicated *Haemophilus influenzae* (*H. influenzae*), *Mycoplasma pneumoniae* (*M. pneumoniae*), and *Cytomegalovirus* (CMV) as microbes carrying peripheral nerve-crossreactive epitopes. A common theme with these microbes is that they express carbohydrate epitopes that mimic glycolipid antigens in peripheral nerves, and autoimmunity against these epitopes is manifested as anti-carbohydrate antibodies. Most of the discussion highlights molecular mimicry in *C. jejuni*. A brief discussion on *H. influenzae*, *M. pneumoniae*, and CMV is also included. Glycans mimicking peripheral nerve glycolipids expressed by these microbes are shown in Figure 20.4.

20.3.1. *Campylobacter* *Jejuni*

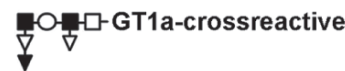

C. jejuni is a gram-negative rod that is one of the most common causes of bacterial gastroenteritis world-wide (Hughes and Rees, 1997; Friedman et al., 2000; Oberhelman and Taylor, 2000). *Campylobacter* infections in US are mostly sporadic and are associated with ingestion of improperly handled or cooked food, particularly poultry products. In northern China contaminated well water was reported as a mode of transmission (McKhann et al., 1993). *C. jejuni* gastroenteritis is reported to be the most frequently recognized event preceding AMAN and other variants of GBS (reviewed in (Hughes and Rees, 1997)). In GBS cases, both stool culture and serologic methods are used to diagnose *Campylobacter* infection, because by the time neurological symptoms develop, the yield of *C. jejuni* from stool culture is relatively low (Nachamkin, 1997). Association of GBS with preceding *C. jejuni* infection was noted in early 1980's (Rhodes and Tattersfield, 1982). Studies indicate that in patients with GBS, the incidence of preceding *C. jejuni* infection varies widely, ranging from 4% in North America to 74% in northern China (Hughes and Rees, 1997; Ho et al., 1999), with an overall prevalence estimated around 30% (reviewed in (Moran et al., 2002)).

Ganglioside-like moieties in *Campylobacter* are contained in its lipopolysaccharide (LPS). *C. jejuni* LPS consists of

Campylobacter jejuni

Haemophilus Influenzae

Mycoplasma pneumonia

CMV

FIGURE 20.4. Glycan structures (mimics) expressed by different microbes that are invoked in molecular mimicry. The term “like” is used when glycan structure has been determined by biochemical/mass spectrometry studies and term “crossreactive” is used when evidence for glycan structure is indirect and based on antibody inhibition or binding studies.

three components: lipid A, the hydrophobic region inserted into the membrane, an oligosaccharide core divided into inner and outer parts, and capsular polysaccharides also called O-chains. Lipooligosaccharide (LOS) is differentiated from LPS by lack of O-chains. In *C. jejuni* it is the oligosaccharide core region that carries ganglioside-like moieties. Since 1990 a large number of studies have characterized the core regions of LPS/LOS of GBS- and enteritis-associated *C. jejuni* strains. These studies demonstrate that different strains or serotypes of *C. jejuni* LPS/LOS contain several ganglioside-like molecules, including GM1-, GD1a-, GalNAc-GD1a-, GM1b-, GT1a-, GD2-, GD3-, and GM2- like structures (Yuki et al., 1992, 1996; Aspinall et al., 1993, 1994a, b; Sheikh et al., 1998;

Nachamkin et al., 2002). Biochemical/structural studies with mass spectrometry have failed to demonstrate a GQ1b-like structure, target antigen for FS, but antibody binding assays with human or murine monoclonal antibodies did show the presence of GQ1b- and GT1a- cross-reactive moieties in *C. jejuni* LPS/LOS (Jacobs et al., 1997, 1995; Yuki et al., 1994). Figure 20.4 shows the ganglioside-like moieties in *C. jejuni* LOS that are implicated in AMAN and FS. Recent studies show that *Campylobacter* has genetic machinery for LOS biosynthesis with relevant genes clustering in a locus. It has been reported that specific polymorphisms in a sialyltransferase gene are associated with preferential expression of GM1- and GD1a- or GQ1b-like moieties. Based on this observation it has been postulated that these genetic polymorphisms determine the specificity of anti-ganglioside antibody response (anti-GM1 and -GD1a or -GQ1b) and clinical phenotype (AMAN or FS).

Despite the relationship of preceding *Campylobacter* infection, we emphasize that GBS is a very rare complication after *C. jejuni* infection: it is estimated that 1 in 1000 cases of *Campylobacter* infection is complicated by GBS (Allos, 1997). Because GBS follows very rarely after *C. jejuni* infection, investigators have examined *Campylobacter* and host-factors that may lead to this complication. Thus, *Campylobacter* strains isolated from patients with GBS and enteritis have been characterized for ganglioside mimicry. It is known that both GBS- and diarrhea-associated isolates carry ganglioside-like moieties and associated synthetic genes, but GBS-related organisms are more likely to do so (Nachamkin et al., 1999, 2002). Notably, studies indicate that expression of ganglioside-like structures in LOS, even when accounting for increased probability of synthetic machinery for ganglioside-like moieties in GBS-associated isolates, is not sufficient by itself to explain the calculated rate of GBS after *Campylobacter* infection (1 in 1000). Some studies indicate that post-*Campylobacter* GBS cases preferentially associate with certain HLA alleles, the significance of these findings remains unclear because of lack of confirmatory studies (Yuki et al., 1991; Rees et al., 1995b). The host properties that could confer susceptibility to GBS after *C. jejuni* infection are not well established.

Clinical studies showing that GBS sera or purified anti-ganglioside antibodies from GBS sera bind to ganglioside-like moieties in the LPS/LOS (Wirguin et al., 1994; Oomes et al., 1995; Sheikh et al., 1998) promulgated the hypothesis that cross-reactive carbohydrate moieties in LOS incite production of these antibodies. This hypothesis has been examined experimentally by immunization of laboratory animals with *C. jejuni* LPS/LOS to induce anti-ganglioside antibodies (Wirguin et al., 1997; Goodyear et al., 1999; Ang et al., 2001a). There is a high level of tolerance to self-gangliosides, and immunizations in experimental animals have generally induced low affinity non-T cell-dependent antibodies of IgM and IgG3 type (non-complement-fixing isotype in mice), despite the use of adjuvants to recruit T cell help (Wirguin et al., 1997; Goodyear et al., 1999; Bowes et al., 2002).

In contrast, serological studies in AMAN and FS indicate class switching to IgG and subclass restriction to IgG1 and IgG3 (complement-fixing isotypes in humans), both usually features of T-cell help. Transgenic mice lacking complex gangliosides are immune naïve to complex gangliosides such as GM1, GD1a, and GQ1b, and immunization with gangliosides or *C. jejuni* LPSs in these animals induces IgG anti-ganglioside antibodies with complement-fixing subclass isotypes, indicating recruitment of T cell help (Lunn et al., 2000; Bowes et al., 2002). These experimental observations suggest that breakdown of tolerance to self-gangliosides might be critical in the pathogenesis of post-*Campylobacter* GBS. Despite these experimental advances the mechanism(s) of anti-ganglioside antibody induction in patients with *Campylobacter* infection remains unclear.

20.3.2. Haemophilus Influenzae

H. influenzae is a gram-negative bacterium that causes human respiratory tract infections. In GBS, preceding infection with *H. influenzae* is rare, ranging between 1% in western Europe to 13% in Japan (Jacobs et al., 1998; Mori et al., 2000; Koga et al., 2005a). In comparison to post-*Campylobacter* GBS, preceding infection with *H. influenzae* is associated with faster recovery, less cranial nerve involvement, and milder disease course (Kuwabara et al., 2001). Based on GBS or FS sera (antibody) binding to LOS/LPS it has been postulated that *H. influenzae* may carry ganglioside-like moieties such as GM1 and GT1a (Koga et al., 2001, 2005a; Mori et al., 1999). Structural/mass spectrometry studies demonstrating ganglioside-like moieties on *H. influenzae* are not yet available. A recent study reports that isolation of *H. influenzae* does not necessarily indicate that this infection is the trigger for induction of anti-ganglioside antibodies because a considerable number (15%) of GBS patients with *H. influenzae* isolated by culture were seronegative for this bacterium, but seropositive for *Campylobacter*. Further, anti-ganglioside antibodies of seronegative patients did not show any crossreactivity with *H. influenzae* LOS (Koga et al., 2005b). Whether immunization with *H. influenzae* triggers induction of anti-ganglioside antibodies in experimental animals remains to be determined.

20.3.3. Mycoplasma Pneumoniae

Antecedent infection with *M. pneumoniae* can be found in 2–12% of patients with GBS (Hao et al., 1998; Jacobs et al., 1998; Ogawara et al., 2000). Studies indicate that some cases of demyelinating form of GBS are associated with *M. pneumoniae* (Hao et al., 1998; Ang et al., 2002). This infection is reported to trigger antibodies against galactocerebroside (GalC), a major glycolipid antigen in myelin, in some patients with GBS. Anti-GalC antibodies have been shown to induce demyelination in experimental animal models (Saida et al., 1979a, b; Hahn et al., 1993). The hypothesis of molecular mimicry is supported by the findings that anti-Gal-C reactivity in GBS sera following

M. pneumoniae infection was specifically inhibited by adding *M. pneumoniae* reagent (Kusunoki et al., 2001). One study has reported the AMAN form of GBS in association with anti-GM1 antibodies and preceding *M. pneumoniae* infections (Susuki et al., 2004). These investigators report that anti-GM1 antibodies bind to lipids extracted from *M. pneumoniae*, suggesting that GM1-like structures are also expressed by this microbe.

20.3.4. Cytomegalovirus (CMV)

In GBS, serological evidence for preceding infection with CMV ranges between 8 and 15% (Dowling and Cook, 1981; Visser et al., 1996; Ogawara et al., 2000; Hadden et al., 2001). Patients with CMV-associated GBS appear to have a different clinical phenotype: significantly younger patients are affected, the disease course is more severe, there is prominent cranial and sensory nerve involvement, and functional recovery is incomplete (Visser et al., 1996). With the availability of modern techniques, PCR is more appropriate to demonstrate infection with CMV. A previous study failed to detect CMV genome in sural nerve biopsies from GBS patients (Hughes et al., 1992) but a recent study demonstrated the presence of CMV DNA in the CSF of about 30% of GBS patients with positive CMV serology (Steininger et al., 2004). Several studies have reported an association of CMV infection with GM2 antibodies in patients with GBS (Irie et al., 1996; Yuki and Tagawa, 1998; Khalili-Shirazi et al., 1999). A recent study showed that anti-GM2 reactivity in GBS sera was abrogated after incubation with fibroblasts infected with a GBS-associated CMV strain, indicating that CMV-infected fibroblasts express GM2-like epitopes recognized by anti-GM2 antibodies (Ang et al., 2000). This intriguing finding raises the possibility that either CMV itself expresses GM2-like epitopes or it induces the expression of this ganglioside in the host cells which renders them immunogenic. The later possibility would suggest that direct molecular mimicry by the infecting agent and target tissue antigens may not be necessary. Besides GM2, antibodies against GalNAc-GD1a and GM1 have also been reported in the setting of CMV infection and GBS (Khalili-Shirazi et al., 1999; Kaida et al., 2001).

20.3.5. Gaps in Molecular Mimicry Hypothesis

Despite the accumulation of significant data supporting the hypothesis of post-infectious molecular mimicry in GBS, clearly several fundamental questions remain unresolved: (1) Infectious agents invoked as triggers for anti-glycolipid antibodies in patients with GBS are microbes that induce gastrointestinal and upper respiratory tract infections in a large number of people but only rare individuals develop GBS after these common infections. (2) What are the mechanism(s) of anti-glycolipid antibody induction in patients with post-infectious GBS? The induction of these antibodies in GBS patients is likely to be substantially different from experimental approaches that involve repeated use of infectious

organism and adjuvants or immune naïve animals to produce disease-associated anti-ganglioside antibodies. (3) Antibodies against GM1, GM2, and GalC can be seen in other neurological disorders or sometimes in normal controls. What are the antibody-related properties that can distinguish between disease-associated and non-disease-associated antibodies? These and other unresolved issues need further research to increase our understanding of post-infectious autoimmune disorders.

Summary

Autoimmunity is implicated in a small but important group of peripheral nerve diseases. These include the acute inflammatory neuropathies referred to as the Guillain-Barré (GBS) and Fisher syndromes. Early recognition and appropriate management of these neuropathies can prevent significant morbidity and mortality. Substantial evidence exists for an autoimmune pathogenesis in GBS and its subtypes. Although most current evidence supports an antibody driven pathogenesis triggered by infection, T-cell and other cellular immune components are crucial effectors of disease particularly in the demyelinating forms of GBS.

21.1. Introduction

Historically, the concept of autoimmunity centers on the inability to adequately identify some of the body's own proteins. In an autoimmune disease, the immune system inappropriately recognizes those proteins leading to a pathologic humoral and/or cell-mediated immune reaction. Both the "self" protein antigens and their site determine the specific end organ damage. Autoimmune diseases are a diverse group of disorders with relatively poorly understood pathogenesis. Often diagnosed as end-organ specific, autoimmune diseases usually involve multiple sites including the nervous system. In addition, more than one autoimmune disease is frequently diagnosed clinically in the same patient (Brinar et al., 2006).

21.1.1. Autoimmune Nervous System Disease Processes

The classic hypothesis predicts that auto-antibodies are the primary mediators of organ damage in any specific autoimmune disorder. However, this simplistic view does not explain the heterogeneous presentation in patients. In many "autoimmune" disorders evidence supports a role for auto-reactive T cells and genetic control of end organ susceptibility. End organ damage may be due to an interaction between innate and adaptive immunity. While the detection of serum auto-antibodies remains a major marker for clinical diagnosis of disease, auto-antibodies to classic antigens are neither required nor sufficient for end organ damage (Bagavant and Fu, 2005). With multi system involvement and specifically nervous system involvement associated with a wide range of autoimmune disorders, etiology and pathogenesis also become more complex.

Immunosuppressant therapies now make many of the autoimmune disorders treatable but not curable. The

role of specific immunotherapies in treatment of specific autoimmune disorders (and not others) will be reviewed. In addition, paradigms relating to the immune system and autoimmune disorders such as the conflicting role of inflammation as both a positive and negative factor and the role of infections in initiating as well as abrogating autoimmunity will be reviewed.

Inflammation is a hallmark of all the autoimmune disorders. The target of either the primary or secondary inflammatory autoimmune response is usually systemic. In Sjogren's syndrome, salivary and lacrimal glands are the primary targets while in rheumatoid arthritis (RA) the primary targets are the synovial joints. Systemic autoimmune responses often go through periods of inflammatory exacerbation and remission. With continuous inflammatory cycles the systemic autoimmune disorder can involve the central nervous system (CNS) demyelination. CNS demyelination can be miss-diagnosed as multiple sclerosis (MS) but more often meets diagnostic criteria for disseminated encephalomyelitis that is the result of vasculitis. CNS demyelination may also be a post-infectious manifestation associated with other autoimmune disorders (Brinar et al., 2006). To understand the transition from a single end organ auto-antibody reaction to multi system involvement that includes the nervous system involves understanding the role of the blood brain barrier and lymphocyte trafficking under inflammatory and pathologic conditions. For example, the increased expression of the matrix metalloproteinase, MMP-9, in the degradation of components of the endothelial extra-cellular matrix is associated with the role of MMPs in vasculitic neuropathy (Gurer et al., 2004).

Vasculitis is a common feature of disseminating autoimmune disorders and refers to inflammation of the blood vessels, both arteries and veins of varying caliber. Neurologically, it is often associated with ischemic injury but may be caused by specific drugs, infectious agents or malignant processes (Younger, 2004). The inflammation associated with vasculitic neuropathy occurs as a hypersensitivity reaction to antigens of perceived non-self proteins. In vasculitic neuropathy, mononuclear cells in the perivascular infiltrate express T cell restricted intracellular antigens,

which induce apoptosis of other inflammatory mononuclear cells and may affect recovery (Heuss et al., 2000). Cyclooxygenase-2 mRNA is upregulated in endoneural macrophages resulting in an increased production of prostaglandins. Thus, cyclooxygenase-2 may be a potential target for therapy particularly early in the autoimmune disease process (Hu et al., 2003). Increased cytokine expression in vasculitic neuropathy positively correlates with neuropathic pain (Lindenlaub and Sommer, 2003) and may be influenced by a differential expression of pain related neurotropic factors and their soluble receptors (Yamamoto et al., 2003). Binding of ligand, N^e –(carboxymethyl) lysine, to the receptor for advanced glycation end products results in activation of the pro-inflammatory transcription factor, nuclear factor-[kappa]B (NF[kappa]B) and subsequent expression of NF-[kappa]B-regulated cytokines. This pathway is hypothesized to play a role in both the initiation and the maintenance of inflammation during vasculitic neuropathy (Haselbeck et al., 2004).

21.1.2. Gender and Autoimmune Disorders

Most autoimmune disorders are highly gender specific (Table 21.1). Sjogren's syndrome affects women more frequently than men at a 9:1 ratio while Crohn's disease affects men and women in approximately equal numbers. Alkylosing spondylitis and Reiter's syndrome usually affect more young white men. Often severity of symptoms and progression are more severe in the gender less commonly affected. While MS affects women more frequently than men in a 2:1 or 3:1 ratio, many affected men have a more aggressive and progressive form of MS than women. A correlation also exists between gender specificity of the autoimmune disease and the efficacy of specific immunosuppressant therapies.

An example of the gender dilemma is illustrated in systemic lupus erythematosus (SLE) an autoimmune disease that occurs more frequently in women than men. The gender difference is attributed to differences in the metabolism of sex hormones or regulation by gonadotropin releasing hormone (GnRH). When it occurs in men, SLE tends to be more severe (Yacoub Wasef, 2004). Recent studies also indicate that SLE may be more common in nonwhite women of child bearing

age. However, evidence collected over the last quarter century indicates that SLE is increasing in nonwhite South African men (Faller et al., 2005).

The gender bias for some autoimmune disease can have prognostic value. In MS, a CNS demyelinating disease, more women are affected (Paty et al., 1998). However, male gender is predictive of a shorter time to reach a need for assisted walking devices. Men also have a higher rate of cerebellar involvement and a higher risk of primary-progressive disease (Whitacre et al., 1999).

21.1.3. Demographics

Specific autoimmune disorders are often associated with racial or ethnic groups. Genetic haplotypes have been identified in association with some autoimmune disorders. However, genetic factors are not enough to explain the heterogeneity in many of the autoimmune disorders. On the other hand, just as gender often correlates with severity or type of symptoms in most autoimmune disorders, race and ethnicity are associated with specific sub groups within a specific autoimmune disorder.

21.1.4. Proposed Mechanisms and Treatment

The presence of autoantibodies explains some of the symptoms of autoimmune disease but not all. Theories on the role of infection (both viral and bacterial), genetic markers and dys-regulation of T and B cell function are all proposed mechanisms for at least one autoimmune disease. Specific mechanisms will be discussed in conjunction with specific autoimmune disorder. However, one of the paradigms associated with autoimmune disease is the role of infections. In some autoimmune disorders, such as Crohn's disease and alkylosing spondylosis, bacterial infections are linked with initiating the disease in genetically susceptible individuals. In others, such as MS, infections are frequently linked with relapses or exacerbations. Conversely, improved hygiene and living condition worldwide have decreased exposure to foreign antigens and infectious agents but the global incidence of autoimmune disorders has increased (Christen and von Herrath, 2005).

Historically, newly diagnosed patients with autoimmune disorders or those with minor symptoms are treated with symptom

TABLE 21.1. Demographics of Autoimmune Disease.

	Incidence by gender women:men	Demographic considerations
Rheumatoid arthritis	2–3:1	Diagnosis usually 17–35 yrs
Sjogren's syndrome	9:1	Diagnosis > 40 yrs
Systemic lupus erythmatosis	8–9:1	Increased in non-white women
Alkylosing spondylitis	<1:1	Increased in young men
Crohn's syndrome	1:1	
Reiter's Disease (Reactive arthritis)	1:1 after enteric infection	Increased in young white men but increasing in undeveloped world
	1:9 after STD	
Psoriasis	Slight increase in women: men	
Multiple Sclerosis	3:1	Diagnosis usually 20–40yrs

specific therapy such as the use of artificial tearing agents for the dry eyes associated with Sjogren's syndrome. As the understanding of the underlying immune mechanisms has improved, treatment of autoimmune disease has increasingly involved the use of immunologic agents. However, a therapy that is effective in one autoimmune disorder may not work in others. Corticosteroids and other compounds that target the inflammation associated with the disorder are an example of therapies that show some efficacy in most autoimmune disorders. Others such as Interferon (IFN) β for MS and the TNF α antagonists for Crohn's disease seem relatively disease specific.

Immunomodulator therapy is commonly used for severe autoimmune disease that is refractive to standard therapy. For example, where activated T cells are implicated, cyclophosphamide is often efficacious. It is immunoablative but not myeloablative, permitting the patient's endogenous stem cells to repopulate the hematopoietic/immune systems (Drachman and Brodsky, 2005). A recent review indicates that over 700 patients have received autologous hematopoietic stem cell transplants (AHSCT) as treatment for severe autoimmune disease primarily as part of phase I/II trials following international guidelines (Tyndall and Saccradi, 2005). The results have led to phase III prospective randomized controlled trials of AHSCT in MS, SLE, and RAs in Europe. In the US, similar trials are planned for systemic sclerosis, MS and SLE. A major concern involves which patients would benefit from such invasive therapy. The early trials of AHSCT for MS involved patients with severely progressive disease. While progression was slowed, areas of disability that were present prior to the AHSCT, as might be expected, persisted (Nash et al., 2003; Kozak et al., 2001; Healey et al., 2004). Results suggest the use of AHSCT in MS patients with much lower disability in an attempt to preserve function and to minimize the risk of further degenerative changes (Burt et al., 2003a). However, there are no quantitative markers to identify early who will develop MS severe enough to warrant AHSCT. Similarly, at the one year follow-up patients with severe Crohn's disease treated with AHSCT had a return of low levels of auto-antibodies. At present AHSCT should only be used in clinical trials at experienced centers and long term benefits are not known. Even though each autoimmune disease has a different immune profile, over one third of transplanted patients have sustained remission and those who relapse often respond to immunotherapy that was ineffective prior to transplantation (Tyndall and Saccradi, 2005).

21.2. Autoimmunity as It Applies to the Nervous System

21.2.1. The Blood-Brain Barrier and Lymphocyte Trafficking

For CNS involvement as the primary or secondary target of an autoimmune disease, activated immune cells must be able to enter and leave the CNS. The route for lymphocyte traffick-

ing across the cerebrovascular endothelium into and out of the brain parenchyma is more complex than in systemic tissue. First, the cerebrovascular unit, blood brain barrier (BBB), is designed as a selective barrier consisting of the endothelial cells and associated basement lamina. Unlike microvessels in many areas, the cerebrovascular microvessel basement lamina is well developed; tight junctions between adjacent cerebrovascular endothelial cells prevent molecular and cellular movement between the cells and perivascular astrocytic end plates are positioned between the microvessels and neuronal axons. Second, the cerebrovascular endothelium is designed to facilitate lymphocyte trafficking including attachment, rolling along the plasma membrane and movement through the endothelial cell. Recent reviews discuss the structure and interactions between the cerebrovascular endothelial cells and astrocytes at the BBB (Anderson and Nedergaard, 2003; Nedergaard et al., 2003; Abbott et al., 2006). One role of the BBB and its cellular constituents is to precisely regulate the micro-environment for neuronal signaling. Rather than acting simply as a barrier, the BBB is a dynamic system where permeability and transport are modulated to control the ionic characteristics of the CNS and regulate its volume. The BBB acts to separate pools of neurotransmitters and neuroactive agents that act within the CNS and in the blood stream so that similar agents can be active without 'cross talk' (Cser and Bundgaard, 1984). In vitro studies indicate that brain endothelium is different from endothelium of peripheral microvessels. Tight junctions are more complex and restrict movement of even small ion such as Na⁺ and Cl⁻ so that the trans-endothelial electrical resistance which is typically 2 to 20 ohm/cm² in the peripheral capillaries can be > 1,000 ohms/cm² in brain endothelium (Butt et al., 1990). Among the molecules that contribute to the tight junction structure are the transmembrane proteins, occludins and claudins. Occludin is a 60–65 kDa protein with a carboxy-terminal domain that can link with zonula occludens proteins and is hypothesized to regulate tight junctions (Hawkins and Davis, 2005). In the BBB expression of the proteins, claudin 3 (often termed claudin 1/3), claudin 5 and possibly claudin 12 appear to play a role in the high transendothelial electrical resistance (Wolberg and Lippoldt, 2002).

There is strong in vitro evidence that astrocytes up-regulate many of the features related to tight junctions as physical and metabolic barriers. Transport barrier function includes regulating expression and polarized localization of transporters including Pgp (Schinkel, 1999) and GLUT1 (McAllister et al., 2001). Polarization of brain endothelial cells or the presence of orientation and apical-basal properties is a characteristic usually seen in epithelial cells but not endothelial cells. The PAR3-atypical protein kinase C (aPKC-PAR6 complex) may be involved in regulating the cell polarity of brain endothelial cells, (Abbott et al., 2006). Metabolic barrier functions are regulated by still other specialized enzyme systems of astrocytes (Abbott, 2002; Hayashi et al., 1997; Sobue et al., 1999).

Complex mechanisms regulate molecular trafficking as they move into and out of the CNS and pathologic conditions

may change this pattern. Since many of the neurologic autoimmune disorders are postulated to involve trafficking of activated T cells across the BBB, the chemokine receptor, CXCR3, has received significant interest. CXCR3 is the receptor for CXCL9/MIG, CXCL10IP-10 and CXCL11/I-TAC and is preferentially expressed on activated Th1 T cells. While CXCR3 is hypothesized to play a role in the trafficking of Th1 T cells, studies in animal models such as EAE and transgenic mice using receptor blockade have been problematic (Liu et al., 2005). The conflicting results indicate that the role of CXCR3 and its ligands may be more complex in some types of CNS inflammation than previously thought.

21.2.2. Inflammation: A Double Edged Sword

While inflammation is associated negatively with vasculitis and autoimmune disease, it is also necessary to protect normal cells from viral and bacterial infection. Many of the therapies that act positively as immunosuppressants have an initial inflammatory response. While IFN β is an effective therapy in the inflammatory phases of MS, the initial response to each injection is an increase in inflammatory cytokines, IL-2 and IFN γ (Elliott et al., 2001). Conversely, natalizumab a therapy that showed great potential in phase I/II trials for aggressive MS by blocking activated lymphocyte trafficking into the CNS was withdrawn because of deaths due to progressive multifocal leukoencephalopathy.

21.3. Autoimmune Diseases with Nervous System Involvement

In reviewing specific autoimmune diseases, the primary involvement is often not the nervous system. However, neurologic symptoms and involvement frequently accompany most autoimmune disorders (Table 21.2).

21.3.1. Rheumatoid Arthritis

21.3.1.1. Epidemiology

Rheumatoid arthritis (RA) is the most common autoimmune diseases and a chronic systemic inflammatory disease affecting both the joints and extra-articular tissue. Often the disease is progressive with the major symptoms including painful, stiffness and swelling of joints culminating in significant morbidity and increased mortality (Khurnana and Berney, 2005). Neurologic complications occur in moderate to severe RA either as a result of disease erosive effects on joints and bones or caused by the disease itself (compressive rheumatoid nodule or rheumatoid vasculitis (Chin and Latov, 2005).

A familial predisposition and genetic markers are linked to an increased risk for developing RA. In the last decade, it became known that there is often an extended period, often years, when specific immunologic markers may be identified before the inflammatory manifestations of RA occur (Masi and Aldag, 2005). Rheumatoid factors and related antibodies occur in conjunction with about half of the presymptomatic manifestations. Significant cigarette smoking is a major risk factor for RA for post-menopausal women and for men. For pre-menopausal onset RA in women, cytokine imbalance and insufficiency of adrenal cortical function may precede inflammatory onset of RA. In men, multiple hormonal and cytokine correlations can be found years before onset of RA implicating a long term activation or dysfunction in the neuroendocrine-immune system (Masi and Aldag, 2005).

21.3.1.2. Multi System Involvement with Emphasis on Neurologic Symptoms

Rheumatoid vasculitis affecting the CNS is rare but may present as seizures, dementia, hemiparesis, cranial nerve palsy, blindness, hemispheric dysfunction, cerebellar ataxia or dysphasia (Vollertsen and Conn, 1990; Ando et al., 1995) Expression of

TABLE 21.2. Primary tissue and neurologic involvement in autoimmune diseases.

	Primary tissue involvement	Neurologic Involvement
Rheumatoid Arthritis	Joints & extra-articular tissue	Rare CNS involvement Peripheral neuropathies common
Sjogren's syndrome	Salivary and lacrimal glands	Variable; Sensory ataxic, painful, peripheral and trigeminal neuropathies common
Systemic lupus erythmatosis	Connective tissue	Variable; transient ischemic attacks, seizures, psychosis, cognitive disorders, dementia and delirium reported
Alkylosing spondylitis	Intervertebral joints and sacroiliac joint	Eye inflammations and caudae equinae related neuropathies
Reiter's Disease (reactive arthritis)	Vertebral joints	>15% develop alkylosing spondylitis or severe arthritis with neurologic sequelae
Crohn's syndrome	Intestinal tract	CNS and peripheral involvement seen in > 30%; neurologic features variable
Psoriasis and psoriatic arthritis	Skin Joints and connective tissue	Peripheral neuropathy related to spinal involvement
Multiple Sclerosis	Central nervous system	Central nervous system

matrix metalloproteinases have been linked to the vasculitic neuropathy associated with RA (Gurer et al., 2004).

Peripheral neuropathies are common in RA. The cervical spine is frequently involved in RA and atlantoaxial subluxation is the most common type of instability (Tumialan et al., 2004). Peripheral neuropathy is present in as many as 70% of patients with advanced RA. Those with RA for more than 10 years and onset after age 50 are particularly at risk (Naranjo et al., 2004). Rheumatoid changes to the synovial joints between the dens and the atlas anteriorly and the dens and transverse ligament posteriorly compress the spinal cord. Patients report neck pain and paresthesia with myelopathic findings on hyperflexia, weakness, gait abnormalities, flexor spasms, sphincter disturbances or sensory changes. The degenerative changes in the cervical spine may also compress the vertebral arteries resulting in vertebro-basilar insufficiency manifested by nausea, vertigo, diplopia and dysphasia (Tumialan et al., 2004).

21.3.1.3. *Hypotheses for Etiology and Treatment*

Inflammation of the synovial joints is the primary symptom in early RA. The dense irregular connective tissue that forms the synovial membrane of the articular capsule thickens. Synovial fluid consists of hyaluronic acid produced by fibroblast-like cells in the membrane and interstitial fluid that may include phagocytic cells filtered from the blood plasma. As the synovial membrane thickens, the synovial fluid accumulates causing pressure and the pain and inflammation characteristic of RA. If the inflammation is untreated, granulation tissue adheres to the articular cartilage and the autoimmune response invades and erodes the cartilage leaving the fibrous tissue to join the ends of the bones. In severe cases, the fibrous tissue ossifies and the bones fuse becoming immobile.

A comprehensive review discusses the therapeutic management of RA (Turesson and Matteson, 2004). Epidemiological studies link extra-articular rheumatoid arthritis manifestations with premature mortality and support aggressive anti rheumatoid therapies for those patients. Cyclophosphamide is favored in patients with systemic rheumatoid vasculitis and methotrexate in those cases with other manifestations of extra-articular rheumatoid arthritis (Turesson and Matteson, 2004). Cyclophosphamide and TNF α inhibitors such as infliximab have some positive success in treatment resistant vasculitis associated with RA (Unger et al., 2003). However, TNF α inhibitors have also been associated with the opposite effect, an induction of extra articular rheumatoid arthritis so their use should be used only in specific cases when close monitoring is in place.

21.3.2. Sjogren's Syndrome

21.3.2.1. *Epidemiology*

Sjogren's syndrome is a common chronic autoimmune disease that affects the salivary and lacrimal glands, with associ-

ated lymphocytic infiltration (Fox, 2005). Primary Sjogren's involves the exocrinopathy alone but Sjogren's can also occur in conjunction with another autoimmune disorder such as RA or SLE. Major symptoms include dryness of the mucous membranes of the mouth, eyes and nose due to the involvement of the lacrimal and salivary glands. Diagnostic criteria require clinical symptoms of dryness, characteristic features on biopsy of a minor salivary gland or auto-antibodies, anti-SS-A or anti-SS-B. Primary Sjogren's syndrome patients also often have antinuclear antibodies.

Numbers vary but it is estimated that between 1 and 4 million people have Sjogren's syndrome (National Institute Arthritis, Musculoskeletal Skin Disease, 2005). The majority of those diagnosed with Sjogren's are women (90%) and the syndrome is usually diagnosed after age 40 but may occur at any age. Sjogren's syndrome affects all races and ethnic backgrounds.

21.3.2.2. *Multi System Involvement with Emphasis on Neurologic Symptoms*

Multi-system involvement may include the skin, lung, heart, kidneys hematological and lymphoproliferative disorders as well as the nervous system, both peripheral and the CNS. The nature of the neuropathies associated with Sjogren's syndrome varies. In an assessment of 92 patients with primary Sjogren's associated neuropathy, the majority of patients (93%) were diagnosed with Sjogren's syndrome after the neuropathic symptoms appeared (Mori et al., 2005). The study of 76 women and 16 men classified their neuropathies into seven forms: sensory ataxic neuropathy (n = 36), painful sensory neuropathy without sensory ataxia (n = 18), multiple mononeuropathy (n = 11), multiple cranial neuropathy (n = 5), trigeminal neuropathy (n = 15), and autonomic neuropathy (n = 3). Clinicopathological observations suggest sensory ataxic, painful and perhaps trigeminal neuropathy are related to ganglioneuropathic processes. Multiple mononeuropathy and multiple cranial neuropathy is more closely associated with vasculitis. Acute or subacute onset of the neuropathy was seen more frequently in multiple mononeuropathy and multiple cranial neuropathy. Chronic progression predominated in the other forms of neuropathy. Sensory symptoms predominate over motor involvement in sensory ataxia, painful sensory, trigeminal and autonomic neuropathy. Motor weakness and muscle atrophy are observed in multiple mononeuropathy, multiple cranial neuropathy and radiculoneuropathy. Autonomic symptoms are often seen in all forms of neuropathy. Sural nerve biopsy specimens (n = 55) reveal variable axonal loss. Large fiber loss predominates in sensory ataxic neuropathy while small fiber loss occurs in painful sensory neuropathy. Perivascular cell invasion is seen most frequently in multiple mononeuropathy followed by sensory ataxic neuropathy. Multifocal T cell invasion is seen in the dorsal root and sympathetic ganglion, perineural space and vessel walls in the nerve trunks.

21.3.2.3 *Hypotheses for Etiology and Treatment*

Both environment and genetics are hypothesized to play a role in the etiology of Sjogren's syndrome. A single gene has not been identified. There is evidence that one gene may predispose Caucasians to the disease since the frequency of the haplotype HLA-DRB1*0301-DRB3*0101-DQA1*0501-DQB1*0201 is significantly increased ($p < 0.001$). Other genes with an increased frequency linked to primary Sjogren's disease in those of Japanese descent include haplotype HLA-DRB1*0405-DRB4*0101-DQA1*0301-DQB1*040 ($p < 0.05$), in those of Chinese descent the haplotype DRB1*0803-DQA1*0103-DQB1*0601 ($p < 0.05$) (Kang et al., 1993). No single class II allele is associated with primary Sjogren's syndrome in the different ethnic groups but a shared amino acid motif in the DQB1 first domain is present in each disease associated haplotype (Kang et al., 1993).

Immunological studies on salivary and lacrimal glands yield conflicting results on the Th1/Th2 balance in Primary Sjogren's syndrome. A recent study in Finnish Caucasians and healthy controls shows no significant difference in the genes encoding for cytokines involved in the regulation of the Th1/Th2 differentiation (Pertovaara and Hurme, 2006). Their findings support the hypothesis that primary Sjogren's syndrome is primarily a Th1 mediated autoimmune disease.

Sjogren's is also hypothesized to be triggered by a virus, which initiates the inflammatory response in lacrimal and salivary glands. The genetic factors play a role in modulating the immune response to the inflammation. In a normally mounted immune response to inflammation, apoptosis of the activated immune cells reverses the process once the virally infected cells are neutralized. In Sjogren's syndrome the normal apoptotic process does not occur due to a combination of genetic and neuroendocrine factors.

The usual therapy includes topical agents that improve moisture and decrease inflammation. Systemic therapy includes steroids and non-steroidal anti-inflammatory agents; disease modifying agents and cytotoxic agents to address the extra-glandular aspects of the disorder.

21.3.3. Systemic Lupus Erythematosus

21.3.3.1. *Epidemiology*

Systemic lupus erythematosus (SLE) is a chronic autoimmune, inflammatory disease of connective tissue that is classified as a rheumatoid disease. Tissue damage can occur in any body system and can range from mild to a rapidly fatal disease. As with many autoimmune disorders, SLE usually has periods of exacerbation and remission. Symptoms include painful joints, low grade fever, fatigue, mouth ulcers, weight loss, enlarged lymph nodes and spleen, sensitivity to sunlight, rapid loss of scalp hair and anorexia. A distinguishing feature is the eruption across the bridge of the nose and cheeks often termed a "butterfly" rash. This and other skin ulcerations were originally thought to resemble the bite of a wolf thus the term

"lupus" became applied to the disorder. The most serious complications of SLE involve inflammation of kidneys, liver, spleen, lungs, heart, gastrointestinal tract and brain.

The prevalence of SLE is 1 in 2,000 persons with females more likely to be affected by a ratio of 8 or 9 to 1. SLE also occurs more frequently in nonwhite women during their child bearing years. Childhood onset of SLE is relatively rare and includes a diverse array of presenting features sufficient to meet American College of Rheumatology (ACR) criteria for SLE. In a review of childhood onset SLE patients in South Africa, the male to female ratio is 1:2.6 overall with a ratio of 1:1.2 if diagnosed under 10 years of age (Faller et al., 2005).

21.3.3.2. *Multi System Involvement with Emphasis on Neurologic Symptoms*

SLE and its most serious complications can involve inflammation of the central nervous system as well as kidneys, liver, spleen, lungs, heart, and gastrointestinal tract. Neuropsychiatric SLE became a case definition to describe patients with cerebral involvement in SLE in 1999 (Ad hoc Am College Rheum, 1999). Those CNS syndromes convincingly attributable to SLE in a comprehensive literature review include stroke, transient ischemic attacks, epileptic seizures, psychosis, cognitive disorder and dementia, and delirium (Jennkens and Kater, 2002). The frequency of an association of specific neurologic symptoms with SLE vary. Kwon (Kwon et al., 1999) report stroke accounts for approximately 20% of neurologic events in SLE and is often secondary to hypercoagulable state or cardiogenic embolism. In a study of gender associated neuropsychiatric symptoms, the most frequent neurologic symptoms in women with SLE are psychiatric symptoms and headaches while men with SLE have more seizures and peripheral neuropathy (Yacoub Wasef, 2004). However, a meta-analysis for headache associated with SLE reviewing the incidence of headache of all types, including migraine, in patients with SLE finds the incidence does not differ from control individuals (Mitsikostas et al., 2004).

21.3.3.3. *Hypotheses for Etiology and Treatment*

Neuropsychiatric SLE symptoms are hypothesized to relate to vascular lesions whereas systemic symptoms may be related to autoantibody-mediated or cytokine mediated impairment of the neuronal function (Katzav et al., 2003). Studies show patients with SLE with neuropsychiatric symptoms have significantly higher antiphospholipid antibody (aPL), particularly anti-cardiolipin antibodies than SLE patients with no neuropsychiatric involvement (Afeltra et al., 2003; Sanna et al., 2003b). The primary target for aPL is beta₂ glycoprotein which may be responsible for small vessel thrombosis, vasculopathy or antibody mediated damage (Katzav et al., 2003; DeGroot and Derksen, 2004). Antibodies to microtubules-associated protein 2 are also 17% higher with neuropsychiatric SLE compared to 4% in controls (Williams et al., 2004).

Severe neurological involvement in SLE particularly during acute onset is a particularly devastating diagnosis. Management of CNS SLE is reviewed by Sanna et al., 2003a. Cyclophosphamide is the treatment of choice for severe acute non-thrombotic CNS disease. Treatment with steroids versus immunosuppressant therapy with cyclophosphamide is evaluated in a controlled clinical trial of 32 SLE patients with onset of severe neuropsychiatric involvement for < 15 days. Induction treatment involved IV methylprednisolone (3 g) followed by either IV monthly cyclophosphamide or IV MP every 3 m for 1 year. Overall response rate was 75% for either treatment but those on cyclophosphamide had a significantly better response to treatment ($p < 0.03$) (Barile-Fabris et al., 2005).

Plasmapheresis is effective in patients with severe neuropsychiatric SLE refractory to conventional treatment. Intrathecal methotrexate and dexamethasone is also beneficial to those patients (Dong et al., 2001; Baca et al., 1999). Positive results of a phase I/II trial of autologous hematopoietic stem cell transplantation (AHST) at Northwestern University in Chicago, IL has led to a phase III ASCT trial. As with other similar trials involving autoimmune disease, the ASCT trial is designed to include standard of care IV pulse cyclophosphamide (Burt et al., 2003b).

21.3.4. Alkylating Spondylitis, Reiter's Disease, Psoriasis, Crohn's Syndrome, and Multiple Sclerosis

This broad group of disorders with autoimmune components and the potential for nervous system involvement were chosen as much for their differences than for their similarities to other autoimmune disorders. In alkylating spondylitis and Reiter's disease the primary end organ target is the vertebral joints but the multi system involvement varies. Both however, affect men more often than women; a characteristic very different than many other autoimmune disease. Psoriasis while usually thought of as a skin disorder is included because the common arthritic involvement is a classic example of multi system involvement in an autoimmune disorder. Crohn's syndrome where the primary target is the gastrointestinal tract affects men and women in equal numbers but has its own pattern of multi system involvement. Finally MS has long been known to have an autoimmune component and a primary target of demyelination in the nervous system but is noteworthy here because of increased evidence of multi system involvement.

21.3.4.1. Alkylating Spondylitis

21.3.4.1.1. Epidemiology

Alkylating spondylitis is an inflammatory autoimmune reactive arthritis with a primary end organ target of the intervertebral joints and the sacroiliac joint at the hip. The characteristic features are a bowed spine and inflamed joints. Compared with 8% of Caucasians as a whole, 95% of people with alkylating spondylitis have the HLA B27 allele. Unlike many autoimmune diseases, alkylating spondylitis is more common in men and has an early onset between 20 and 40m years of age.

21.3.4.1.2. Multi System Involvement with Emphasis on Neurologic Symptoms

Alkylating spondylitis means "stiff vertebra" and is a reactive arthritis that may be triggered by infection. Alkylating spondylitis can cause complications that involve some aspect of the nervous system. Almost 40% of people with some type of spondylitis will experience inflammation of the eye (iritis or anterior uveitis) that include symptoms of sensitivity to light and skewed vision along with typical inflammatory symptoms of redness and pain. Rarely those with advanced alkylating spondylitis will develop cauda equine syndrome, a scarring of the nerve bundles of the cauda equine at the base of the spine. Depending on the nerves involved, urinary dysfunction, pain and weakness in the lower extremities as well as bowel and sexual dysfunction may result.

21.3.4.1.3. Hypotheses for Etiology and Treatment

B27, the HLA allele proposed to be involved in alkylating spondylitis, shares an epitope with an enzyme from *Klebsiella pneumoniae*, a common intestinal Gram negative bacterium. Molecular mimicry is thought to result in cross-reactive antibody formation, joint inflammation and spinal damage. Along with many of the immunotherapies described for other similar arthritic autoimmune disorders, alkylating spondylitis is treated with anti-inflammatory medications and a low carbohydrate diet to reduce intestinal *K. pneumoniae* levels.

21.3.4.2. Reiter's Syndrome (Reactive Arthritis)

21.3.4.2.1. Epidemiology

Reiter's Syndrome is an inflammatory arthritis that produces pain, swelling, redness and heat in the joints. It is one of a family of arthritic disorders, called spondylarthropathies, affecting the vertebral joints. The symptoms of Reiter's disease include fever, weight loss, skin rash, inflammation, ulcerations, and pain. Unlike many autoimmune disorders, Reiter's syndrome usually affects young white men between the ages of 20 and 40.

21.3.4.2.2. Multi System Involvement with Emphasis on Neurologic Symptoms

Reiter's syndrome may affect the skin, eyes, bladder, genitalia and mucous membranes throughout the body so that it can initially share characteristics similar to many other autoimmune diseases.

21.3.4.2.3. Hypotheses for Etiology and Treatment

The exact cause is unknown, but there appears to be a genetic link. About 75% of those with the tendency to develop Reiter's syndrome have the same gene marker, HLA-B27, described in the previous description of alkylating spondylitis. There is also an environmental or infectious component. Reiter's disease can develop in at risk individuals following an infection in the intestines, genital or urinary tract. Bacteria implicated as potential causes of Reiter's syndrome include Chlamydia,

a sexually transmitted bacterium and a wide group of bacteria associated with GI infections including *Salmonella*, *Shigella*, *Yersinia* or *Campylobacter*. Reiter's syndrome usually develops within 2–4 weeks after a bacterial infection in susceptible individuals. While Reiter's syndrome typically has a limited course with symptoms lasting 3 to 12 months, it may recur. For approximately 15–20% of those affected, Reiter's develops into a chronic and often severe arthritis or spondylitis.

The use of NSAIDs and other anti-inflammatory therapies are similar to those used in other autoimmune arthritic disorders. Corticosteroid injections for severe pain and inflammation at specific joints are standard therapy. For severe forms of the disease immunomodulating anti-rheumatic drugs such as methotrexate and sulfasalazine are effective. As with other similar disorders, the biologic TNF α inhibitors are currently prescribed for severe Reiter's syndrome.

21.3.4.3. *Psoriasis*

21.3.4.3.1. Epidemiology

Psoriasis is a chronic autoimmune disease with the skin as a primary target and with both genetic and T cell mediated characteristics. Normally, keratinocyte stem cells divide in the deepest layer of the skin's epidermis, the stratum basale, to form immature keratinocytes. These keratinocytes slowly mature and migrate toward the skin surface accumulating more keratin as they go and eventually undergoing apoptotic cell death before being shed to make room for underlying cells. Epidermal growth factor (EGF) plays a major role in regulating the growth process. The cycle, from cell division to apoptosis and shedding usually takes about 30 days. In psoriasis, the keratinocytes move more quickly from the stratum basale to the stratum corneum of the epidermis where they are shed in as little as 7–10 days. Abnormal keratin is associated with these immature keratinocytes that form flaky, scales or red lesions at the skin surface. That can be inflamed and itch, bleed, crack and be painful.

About 2.1% of the U.S. population has psoriasis or more than 4.5 million adults in the U.S. Diagnosis usually is between ages 15 and 35.

21.3.4.3.2. Multi System Involvement with Emphasis on Neurologic Involvement

Psoriasis generally appears at the joints, limbs and scalp but may appear anywhere on the body. At least 10% those with psoriasis develop psoriatic arthritis, a degenerative disease of the joints and connective tissue. Approximately 1 million people in the U.S. have psoriatic arthritis. Psoriatic arthritis usually develops between the ages of 30 and 50 but can develop without the lesions characteristic of psoriasis (Natl Psoriasis Foundation, 2005, Specific forms of psoriasis, psoriasis.org). Of those with psoriatic arthritis, about 20% will develop spinal involvement. The inflammation associated with spinal involvement can lead to vertebral fusion as in ankylosing spondylitis.

21.3.4.3.3. Hypotheses for Etiology and Treatment

Those patients who develop psoriatic arthritis with spinal involvement are most likely to test positive for the HLA-B27 genetic marker also implicated in ankylosing spondylitis and Reiter's syndrome.

The type of lesion and whether the patient also has psoriatic arthritis are important issues in determining therapy. Steroid topical creams, cyclosporine and methotrexate are useful in treatment of psoriasis. Oral tazarotene, a non-biologic retinoid is pending FDA approval for moderate to severe psoriasis. As with most autoimmune disorders, different patients respond differently and newer more targeted therapies are important goals.

Biologically engineered drugs that target proteins associated with the inflammatory response have recently become important in treatment of both psoriasis and psoriatic arthritis. In 2003, Biogen's alefacept (Amevive), a T cell targeted therapy, became the first biologic drug approved for treatment of psoriasis. It was followed by Genetech's efalizumab (Raptiva). Tumor necrosis factor (TNF) α antagonists are taking the forefront with several receiving FDA approval in the last few years. The FDA approved the TNF α inhibitor, etanercept (Enbrel) for treatment of chronic, moderate to severe plaque psoriasis in May, 2004 (FDA, 2004) and it shows both clinically significant and patient reported positive outcomes (Krueger et al., 2005). Etanercept was previously approved for psoriatic arthritis (Nestorov et al., 2004). Subcutaneously administered etanercept in patients with psoriasis at either 50mg once weekly or 25mg twice weekly indicate similar efficacy and safety profiles (Feldman et al., 2005). Centocor's infliximab (Remicade) and Abbot Laboratories' adalimumab (Humira) are also TNF α inhibitors under investigation for psoriasis and psoriatic arthritis (Weinberg et al., 2005). A major concern of the TNF α antagonist therapies is a possible link to demyelinating disease. Because autoimmune disease often does not occur as a single entity, it is imperative to screen and follow those on the therapy for symptoms of demyelinating disease (Sukal et al., 2006).

21.3.4.4. *Crohn's Disease*

21.3.4.4.1. Epidemiology

An estimated 500,000 Americans have Crohn's disease, an inflammatory bowel syndrome (IBS) that causes chronic inflammation of the intestinal tract. Unlike many autoimmune diseases, Crohn's disease affects men and women equally. About 20% of people with Crohn's disease have a blood relative with some form of IBS. Crohn's disease and ulcerative colitis are similar and are often mistaken for one another. Both involve inflammation of the lining of the digestive tract, and both can cause severe bouts of watery or bloody diarrhea and abdominal pain. However, Crohn's disease can occur anywhere in the digestive tract, often spreading deep into the layers of affected tissues. Ulcerative colitis, on the other hand, usually affects only the lining of the large intestine (colon) and rectum.

21.3.4.4.2. Multi System Involvement with Emphasis on Neurologic Involvement

CNS and peripheral nervous alterations in patients with Crohn's disease is reported to be as high as 33.2% (Santos et al., 2001) with almost 20% having a direct causal relationship with the Crohn's disease. Other neurologic features associated with Crohn's disease include peripheral neuropathy (axonal, demyelinating and autonomic), myopathies, pseudotumors cerebri, papilledema, psychiatric disorders (anxiety, phobia and depression) and an association with syndromes such as MS, Cogan's syndrome, Melkersson Rosenthal syndrome, connective tissue disorders and vasculitis. In a retrospective study of peripheral neuropathy associated with inflammatory bowel disease, demyelinating neuropathy is associated with almost 30% of the cases (Gondim et al., 2005).

21.3.4.4.3. Hypotheses for Etiology and Treatment

Mutations in the NOD2/caspase recruitment domain 15 (CARD15) and in the Toll-like receptor 4 (TLR4) gene are associated with an increased susceptibility for Crohn's disease (Leshinsky-Silver et al., 2005).

The neurologic involvement in Crohn's disease can be attributed to several mechanisms including autoimmunity. For the predominant arterial cerebrovascular involvement, the state of hypercoagulation secondary to thrombocytosis and increase in factor V, VIII and fibrinogen are probable mechanisms. However, since anti-phospholipid antibodies and lupus anticoagulant are confirmed in many cases, autoimmune mechanisms are also involved (Santos et al., 2001).

There's no known medical cure for Crohn's disease. However, strong evidence based efficacy of pharmacological and biological therapies has greatly reduced the signs and symptoms of Crohn's disease and even bring about a long-term remission. Sulfasalazine, sulfa-pyridine linked to 5-aminosalicylic acid (5-ASA) via an azo bond, is a mainstay of therapy but is associated with fever, rash, hemolytic anemia, hepatitis, pancreatitis, paradoxical worsening of the colitis and reversible sperm abnormalities (Stein and Hanauer, 2000). Newer 5-ASA agents deliver the active agent, sulfasalazine while minimizing the adverse effects. Olsalazine may cause secretory diarrhea and uncommonly hypersensitivity reactions including a similar worsening of the colitis as well as pancreatitis, pericarditis and nephritis.

Corticosteroids are commonly prescribed for moderate to severe Crohn's disease with short term efficacy probably related to their effect on inflammation. Anti-bacterials are commonly used as primary therapy in Crohn's disease. Common adverse effects of metronidazole are nausea and a metallic taste, however peripheral neuropathy may result from long term use. Ciprofloxacin and similar antibacterials can be beneficial in those patients intolerant to metronidazole.

Crohn's disease patients treated with systemic steroids or azathioprine show significant improvement in patient quality of life scores (Bernklev et al., 2005). However, azathioprine

and mercaptopurine are associated with pancreatitis in 3–15% of Crohn's patients. The pancreatitis resolves upon drug cessation. Their effect on bone marrow suppression is dose related. (Stein and Hanauer, 2000).

Biologic agents targeting specific sites in the immunoinflammatory cascade are being used to treat Crohn's disease. TNF α antibody therapies such as infliximab, are a standard therapy for severe Crohn's disease, Thalidomide whose effect is partially mediated by down regulation of TNF α has efficacy in previously refractory Crohn's patients (Ginsberg et al., 2001).

Autologous hematopoietic stem cell transplantation (AHSCT) has undergone phase I/II trials for severe Crohn's disease (Craig et al., 2003). While clinical remission occurred as a result of AHSCT, some evidence of minor laboratory abnormalities and slight inflammation of the colon on colonoscopy were reported at the 1 year post transplant follow up.

21.3.4.5. Multiple Sclerosis (MS)

21.3.4.5.1. Epidemiology of MS

MS is a chronic neurologic disease associated with demyelination and death of neuronal axons. Multiple plaques or scars form within the CNS resulting in a wide range of neurological deficits. Because of the role of demyelination in the disease, it is frequently classified with autoimmune disorders. Information on the neuroimmunologic aspects of the various types of MS are covered in a previous chapter.

The prevalence of MS varies considerably around the world with an increased prevalence historically associated with distance from the equator. Kurtzke classified regions of the world according to prevalence: a low prevalence was considered less than 5 cases per 100,000 persons, an intermediate prevalence was 5 to 30 per 100,000 persons, and a high prevalence was more than 30 per 100,000 persons (Kurtzke, 1991). The prevalence is highest in northern Europe, southern Australia, and the middle part of North America (Wynn et al., 1990; Cottrell et al., 1999; Rosati et al., 1996; Svenningsson et al., 1990; Cook et al., 1985; Midgard et al., 1991). Both genetic and environmental factors are associated with MS. Evidence that genetic factors have a substantial effect on susceptibility to MS is unequivocal. A concordance rate of 31% among monozygotic twins is approximately six times the rate among dizygotic twins (5%) (Sadovnick et al., 1993). The magnitude of the relative risk of MS is associated with the frequency of the HLA-DR2 allele in the general population (Jersild et al., 1973). Populations with a high frequency of the allele have the highest risk of MS. Studies of candidate genes have targeted individual genes with microsatellite markers with the use of association and linkage strategies (Sawcer et al., 1996; Haines et al., 1996; Ebers et al., 1996; Kuokkanen et al., 1997). Rivera (2004) reports that MS is a polygenic disease associated with Class I and Class II HLA antigens. The genes considered most likely associated with MS are found in groups with A3, B7, DR2, and DQW1 haplotypes. These particular haplotypes are prominent in Northern and Central European populations (Caucasians) and rare in East

Asians, Black Africans, and aboriginal Australians. However, while these particular ethnic groups have an increased incidence of MS, identical twin studies show only a 30% correlation in disease occurrence in individuals sharing the same DNA and environmental factors. Epidemiological genetic studies show a relational rather than a causative effect (Barcellos et al., 2002). While regions of interest have been identified, none have been linked to MS with certainty.

21.3.4.5.2. Multi System Involvement with Emphasis on Neurologic Syndromes

The characteristics of MS are covered in previous chapters. In general, MS is a disease of the CNS with other systems involved when neuronal connections are disrupted. As a result, symptoms vary widely. Outcome measures and progression are reviewed in conjunction with chapter 3.1.2 on the therapeutic measures available for treatment of MS.

21.3.4.5.3. Hypotheses for Etiology of MS

Demyelination is a pathological hallmark of MS. Multiple sclerosis lesions stand out as areas of brain white matter completely or partially devoid of myelin. Examined posthumously or by MRI, lesions were originally classified as inactive (little or no evidence of myelin breakdown), subacute (numerous lipid macrophages present at the edges of demyelinated tissue) or acute (numerous lipid macrophages and macrophages containing undigested myelin debris present throughout the demyelinated tissue) (Prineas et al., 1984). Subacute lesions are the most commonly observed. As early as 1958, degenerating myelin was described as irregular swelling of sheaths followed by fragmentation into particles and balls of myelin, later phagocytosed by scavenging microglia (Greenfield, 1958). Lesions have a predilection for the optic nerves, periventricular white matter, brain stem, cerebellum and spinal cord white matter and they often surround one or several medium-sized vessels (Lassmann, 1998). Patients with primary progressive MS often have lesions in the spinal cord, which usually manifest clinically as progressive paraparesis (Bruck et al., 2002). Currently, different patterns of demyelination can be distinguished, including demyelination with relative preservation of oligodendrocytes, myelin destruction with concomitant and complete destruction of oligodendrocytes or primary destruction or disturbance of myelination cells with secondary demyelination (Lucchinetti et al., 1996).

Inflammatory cells associated with MS lesions are typically perivascular in location, but they may diffusely infiltrate the parenchyma of the CNS. The composition of the inflammatory infiltrate varies depending on the stage of demyelinating activity. In general, it is composed of CD4 and CD8 lymphocytes and macrophages; the latter predominate in active lesions. Experimental *in vitro* and *in vivo* models of inflammatory demyelination suggest that diverse disease processes, including autoimmunity and viral infection, may induce MS-like inflammatory demyelinated plaques (Hohlfeld et al., 1995; Olsson, 1995). Activated CD4 T

cells specific for one or more self antigens are believed to adhere to the luminal surface of endothelial cells in CNS venules and migrate into the CNS at the time of disruption of the blood brain barrier. This process is followed by an amplification of the immune response after the recognition of target antigens on antigen presenting cells. Antibody mediated processes may have an important role in the pathogenesis of MS. Activated macrophages and microglial cells may mediate degradation of myelin and damage oligodendrocytes by production of proinflammatory cytokines. Other factors potentially toxic to oligodendroglial cells include soluble T cell products (such as perforin), the interaction of Fas antigen with Fas ligand, cytotoxicity mediated by the interaction of CD8 T cells with class I major histocompatibility complex antigens on antigen presenting cells, and persistent viral infection (Lucchinetti et al., 1998). Theories on a role for viral infections continue to postulate enhanced sensitization to myelin or CNS autoantigens in childhood and subsequent infection that activates these sub-threshold T cells during adulthood to initiate myelin injury (Raine, 1984; Haegert, 2003). One example is the two hit infectious hypothesis proposed by Haegert (2003) that proposes that a common virus infects the thymus during childhood and is followed by heterogeneous pathogens that fully activate those T cells during adulthood.

Axonal injury may occur not only in the late phases of MS but also after early episodes of inflammatory demyelination (Lucchinetti et al., 1999; Trapp et al., 1998; Bitsch et al., 2000; De Stefano et al., 2001). Gray matter lesions and axonal injury in normal appearing white matter are reported in MS implying that axonal injury could trigger demyelination (Tsunoda and Fujinami, 2002). The pathogenesis of this early axonal injury is still unclear.

Both inflammatory and neurodegenerative components may contribute to the clinical profile of MS. Inflammation appears to be caused by overactive pro-inflammatory T helper 1 cells, initiating the inflammatory cascade. Current IFN β and glatiramer acetate are most effective in this inflammatory phase of MS. Recent evidence also shows that inflammation may not only be destructive but may also play a part in tissue repair (Grigoriadis et al., 2006).

21.4. Emerging Concepts

Autoimmune disorders are increasing in the general population. With their increase comes an increase in neurologically involvement. While the plethora of new therapies approved in the last 15 years have made many autoimmune diseases treatable, more progress is needed to halt long term progression.

Potential therapeutic benefits of antioxidants to reduce intracellular oxidative stress have not yet been evaluated in vasculitic neuropathy associated with autoimmune disease. Such anti-oxidants as vitamin E, α -lipoic acid or benfotiamine may be effective in interrupting the pro-inflammatory transcription factors and subsequent NF- κ B regulated cytokines that initiate and maintain inflammation associated with vasculitic neuropathy (Haselbeck et al., 2004).

Summary

The general characteristics of autoimmune disease with the implications for neurologic involvement are reviewed. Areas of concentration include the role of inflammation and vasculitis as hallmarks of autoimmune disease in general and the role of a breach of the blood brain barrier with lymphocyte trafficking as specific to involvement of the nervous system. The epidemiology, system involvement including aspects of the nervous system, and current hypotheses for etiology and treatment are discussed for the following autoimmune conditions: Sjogren's Syndrome, Systemic Lupus Erythematosus, Alkylosing Spondylitis, Reiter's Disease, Psoriasis, Crohn's Disease and Multiple Sclerosis.

Review Questions/Problems

- This molecule is hypothesized to be involved in degradation of the endothelial extra cellular matrix in vasculitic neuropathy.**
 - Integrin
 - Matrix metalloproteinase
 - TNF α
 - NF-kappa B
- This autoimmune disease affects men more frequently than women.**
 - Multiple sclerosis
 - Crohn's Disease
 - Reiter's Disease
 - Lupus erythematosus
- An autoimmune disease linked directly to an infectious etiology.**
 - Psoriasis
 - Rheumatoid arthritis
 - Alkylosing spondylitis
 - Systemic Lupus erythematosus
- Which of the following is NOT a structural/functional characteristic of the cerebrovascular endothelium?**
 - Extensive tight junctions
 - Polarization apical-basal orientation of endothelial cells
 - Association with astrocytic end plates
 - Lower trans-endothelial electrical resistance
- Inflammation of the synovial joints in rheumatoid arthritis includes this change in the synovial fluid.**
 - Influx of macrophages and activated T cells
 - Loss of hyaluronic acid
 - Thinning of the synovial membrane
 - Presence of the bacterium *Klebsiella*
- HLA B27 allele has been identified in those at greater risk for all except this autoimmune disease.**
 - Alkylosing spondylitis
 - Psoriatic arthritis
 - Reiter's disease
 - Crohn's disease
- The primary type of nervous system involvement in Sjogren's syndrome is**
 - Spinal cord column involvement
 - Sensory ataxic neuropathy
 - Cervical cord involvement at the atlanto-axis junction
 - Autonomic neuropathy
- In systemic lupus erythematosus, this is a common neurologic involvement due to the chronic hyper-coagulable state.**
 - Autonomic neuropathy
 - Dementia
 - Headache
 - Stroke
- Reiter's disease commonly is diagnosed within this age range.**
 - <20
 - 20–40
 - 40–60
 - >60
- Neurologic involvement in Crohn's disease**
 - Is relatively rare (<5%)
 - Usually occurs in 20%–30% of Crohn's patients
 - Occurs in over 90% of Crohn's cases
 - Is virtually always a peripheral neuropathy
- Compare the gender distribution of those diagnosed with Multiple Sclerosis, Crohn's disease and Alkylosing Spondylitis**
- Autologous hematopoietic stem cell transplantation has undergone phase I/II trials for several autoimmune disorders. Aside from its invasive nature discuss the pros and cons for its use.**
- Discuss the general mechanism of action for biologicals such as infliximab and etanercept.**
- Discuss the different hypothesized etiologies for neuropsychiatric SLE versus systemic SLE neuropathies.**
- Discuss the postulated role of molecular mimicry in Alkylosing Spondylitis.**
- What is the typical short and long-term course of Reiter's disease?**
- Thalidomide is receiving new interest for use in some autoimmune conditions. What is the history and concern for its use?**
- What is the anatomic basis for psoriasis in the skin?**

19. Discuss how inflammation is both a positive and negative factor in autoimmune disorders.

20. Discuss the causes of vasculitis as it relate to vasculitic neuropathy.

NeuroAIDS

Yuri Persidsky

Keywords Anti-retroviral therapy; HIV-1 associated dementia; Blood–brain barrier; HIV-1 encephalitis; Chemokine macrophage; HIV-1

22.1. Introduction

HIV-1 infection of central nervous system results in significant cognitive abnormalities. While underlying mechanisms of such impairment are still not completely understood, chronic neurotoxin production (pro-inflammatory factors and viral proteins) by virus-infected macrophages are considered to be the cause. A better understanding of HIV-1 neurobiology as it is driven by virus replication and anti-viral immunity will continue to drive the development of new therapeutic strategies to combat cognitive decline.

22.2. Clinical Manifestations, Epidemiology, and NeuroAIDS Disease Evolution in the Antiretroviral Era

22.2.1. Clinical Presentation and Epidemiology

The clinical and neuropsychological disease complex called HIV-1 associated dementia (HAD) affects the frontal-subcortical brain regions. Cognitive, motor and behavioral impairments are characterized by deterioration of fine motor coordination and speed, attention, processing speed, executive function, learning efficiency and working memory (Grant et al., 1995; Heaton et al., 1995). Three forms of disease are manifest, including (1) frank HAD, characterized by severe dysfunction that affects everyday cognitive function; (2) mild neuro-cognitive disorder with impairment in two or more cognitive functions with modest interference with everyday function (equivalent to minor cognitive motor disorder, MCMD); and (3) asymptomatic neuro-cognitive impairment, without apparent effect on everyday function.

One quarter of adults and 50% of children developed significant neuro-cognitive complications as a consequence of infection at a period of profound immunosuppression or the acquired immunodeficiency syndrome (AIDS) before the introduction of anti-retroviral therapy (Navia et al., 1986). While subclinical metabolic and structural abnormalities are detectable in neurologically asymptomatic subjects, overt HAD develops as a late complication of progressive viral infection (Koralnik et al., 1990). Proton magnetic resonance spectroscopy (MRS) shows significant metabolic abnormalities in the frontal white matter, basal ganglia, and parietal cortex of HIV-1 patients with HAD compared to neurologically asymptomatic or seronegative controls (Chang et al., 2004). Such MRS changes are not only for HAD. Indeed, HIV-1-infected individuals with normal cognitive function show higher glial marker myoinositol-to-creatine ratio (MI/Cr) in the white matter than seronegative control subjects. Nonetheless, HAD patients show further increased MI/Cr in the white matter and basal ganglia together with a reduction in the neuronal marker N-acetyl aspartate (NAA)/Cr in the frontal white matter. Glial activation likely occurs during all stages of HIV-1 infection, whereas further inflammatory activity in the basal ganglia and neuronal injury in the white matter is associated with the development of cognitive impairment. Host genetic factors likely play a role (e.g., polymorphisms in the promoters of tumor necrosis factor, TNF- α or monocyte chemo-attractive protein, MCP-1) in disease onset and progression but their contribution to HIV-associated cerebral injury require further study (Gonzalez et al., 2002; Letendre et al., 2004).

22.2.2. Disease Evolution in the Era of Anti-Retroviral Therapy

Introduction of anti-retroviral therapy considerably changed the clinical evolution of HIV-1 infection (Palella et al., 1998). Anti-retroviral therapy has diminished the incidence and prevalence of major opportunistic infections and resulted in

improvement in survival rates. 10–15% of patients are now over 50 years of age and with continued advances in treatment, many will reach normal life expectancy (Navia and Rostasy, 2005). As survival rates improved other co-morbid factors emerged in disease evolution including the effects of aging, chronic infection and neurotoxic effects of anti-retroviral medicines themselves. Indeed, nucleoside reverse transcriptase inhibitors (NRTIs) suppress HIV-1 replication, but are also associated with mitochondrial toxicity (Schweinsburg et al., 2005). Reduction in neuronal metabolism was found in individuals taking NRTIs, didanosine and/or stavudine as a result of depleted brain mitochondria and/or alterations in cellular respiration (Schweinsburg et al., 2005).

Anti-retroviral therapy has resulted in decrease in HIV-1 RNA load and in neuroimmune activation, particularly in the cerebrospinal fluid (CSF) (e.g., β 2 microglobulin, quinolinate), as well as a decline in the severity and incidence of dementia. Anti-retroviral-treated patients show enhanced attention, executive performance and psychomotor speed when compared those who have not received treatments (Sacktor et al., 2002). Onset of mild cognitive-motor impairment is postponed by anti-retroviral therapy; however, the incidence of mild HAD may increase over time and cognitive impairment can occur at higher CD4 counts (Sacktor et al., 2002). Development of neurovirulent and anti-retroviral-resistant HIV-1 strains was suggested due to the re-emergence of leukoencephalopathy (Langford et al., 2002), and the compartmental differences between peripheral blood and brain isolates found associated with the presence of discordant virus resistance. This suggested autonomous replication of HIV-1 and the independent evolution of drug resistance within the central nervous system (CNS) (Strain et al., 2005). Discordance of resistance was associated with severity of neuro-cognitive deficits. Low CD4+T cell counts were linked to neuro-cognitive impairment and to discordant resistance patterns. Metabolic abnormalities observed by MRS have continued in subjects on anti-retroviral therapy despite significant improvement in CD4+T cell counts (≥ 300 cells/ml) and suppression of plasma and CSF viral loads (Chang et al., 2003). These studies suggest that HAD has evolved from a subacute, rapidly progressing disease to one more subtle indicating that peripheral suppression of HIV-1 translates into improvement of motor-cognitive function.

22.3. Neuropathology

22.3.1. HIV Encephalitis

It is well accepted that HIV encephalitis (HIVE) is characterized by the presence of HIV-1 infected macrophages in the brain, resulting in the microgliosis and microglia activation (Figure 22.1A), formation of multi-nucleated giant cells (MNGC, Figure 22.1B), and astrogliosis (Figure 22.1C) (Koenig et al., 1986; Budka et al., 1991). Brain mononuclear phagocytes (MP, perivascular macrophages and microglia) are the primary viral targets in the CNS (Figure 22.1D, E); however, restricted viral infection have been detected in other cell populations includ-

ing astrocytes (Trillo-Pazos et al., 2003). Infection of other cell types (neurons, oligodendrocytes, endothelial cells) reported initially remains controversial. While brain HIV-1 infected MP are most abundant in the frontal cortex, basal ganglia and white matter (Wiley, 1995), less prominent infection is present in the limbic system and brainstem (Masliah et al., 2000) or even white matter of cerebellum seen in severe HIVE. The best correlate to the clinical manifestations of HAD is the number of activated macrophages in the CNS (Glass et al., 1995). Although most patients with HIVE have HAD, not all HAD patients have HIVE (Glass et al., 1995). Even minimal increases in the numbers (Cherner et al., 2002) and perhaps even more importantly, the level of MP immune activation, may affect neurological dysfunction (Persidsky et al., 1999).

Virus likely enters the CNS through infected monocytes and macrophages destined to become brain-resident MP or perivascular macrophages (Davis et al., 1992) or within lymphocytes. It is assumed that HIV-1 enters early after primary infection (at a peak of primary viremia), and HIV-1 infection persists at low levels due to immune privileged status of the CNS. The importance of MP in the neuropathogenesis of HIV-1 brain infection is underscored by the emergence of specific monocyte subsets in the peripheral blood of HAD patients. These cells can, but do not always, express CD14/CD16 and CD163 surface markers (Figure 22.1F, G) and demonstrate enhanced ability to migrate and secrete neurotoxins (Pulliam et al., 1997; Luo et al., 2003). The appearance of this monocyte subset in blood coincides with decreased anti-retroviral peripheral immune responses and precedes development of encephalopathy as demonstrated in pediatric patients (Sanchez-Ramon et al., 2003). Immune activation and failing adaptive immune responses are associated with enhanced monocyte migration through the BBB and the secretion of a variety of immune and viral factors known to affect neuronal function (Gendelman, 2002). Viral load, HIV-1 evolution and sequestration in the CNS suggest that virus replication may be compartmentalized in brain. A number of mechanisms are likely to be involved in the response to therapy in CNS, including among others, the trafficking of cell populations supporting viral replication between blood, CNS and CSF, and the role of the anatomical brain barriers in limiting the access of antiretroviral drugs into the CNS/CSF. A potential risk associated with compartmentalization of HIV infection is of an incomplete suppression of virus replication in the CNS, thus creating the ground for local development of anti-retroviral drug resistance and reseeding blood/peripheral tissues with virus during interruptions of therapy.

There was evidence of HIVE in all patients with MCMD or HAD and 80% of the cases with mild impairment at autopsy (Cherner et al., 2002). Among patients who were neuropsychologically normal at the time of testing, 45% had mild HIVE at death. When all neuropsychologically impaired patients were grouped together, 95% of impaired subjects were found to have HIVE. The correlation between the measure of brain viral burden and the clinical scores of neuro-cognitive deficits showed a significant association. Since most of the correlations between HIV-1 levels and cognitive status were of mod-

FIGURE 22.1. Neuropathologic manifestations of HIV-1 infection. (A, B) Increased amount of activated brain MP (microglia and macrophages including giant cells) positive for MHC class II (HLA-DR). (C) Wide-spread astrogliosis (GFAP-positive astrocytes) is seen in the areas of the most prominent MP infiltration. (D) Perivascular macrophages and (E) microglia are productively infected HIV-1 p24-positive cells in the brain. (F,G) Infiltration of CD163⁺ monocytes/macrophages is a hallmark of HIVE (purple) resulting in injury of BBB indicated by decrease of staining for brain endothelial marker, breast cancer resistant protein (brown). (H) Leukoencephalopathy is characterized by massive monocyte/macrophage infiltration and tissue damage. (I) CD8⁺ T lymphocytes (purple) accumulate around HIV-1 p24-positive brain MP (brown). Original magnification: panels A, B, D, E, G $\times 200$; panels C, F, H $\times 100$; panel I $\times 400$.

erate strength suggests that other factors might also contribute to and mediate the severity of the dementia. Among them, levels of macrophage infiltration and activation in the CNS and the extent of damage to the synapto-dendritic structure of neurons (Glass et al., 1995; Masliah et al., 1997, 2000). Other factors to be taken into account in these clinico-pathological studies are the interval between clinical examination, and antiretroviral status and death.

22.3.2. Neuropathology in the Anti-Retroviral Era

Introduction of anti-retroviral therapy also impacted the patterns in HIV-related neuropathology in the past decade. Anti-retroviral therapy resulted in a decline in opportunistic infections of the CNS and neoplasms, and treated individuals survive longer. This is accompanied by an increase in the frequency of chronic forms of HIVE (Langford et al., 2002; Cysique et al., 2004). Everall et al.

(2005) described the emerging variants of HIV neuropathology in ART-treated patients including (1) aggressive forms with severe HIVE and white matter injury, (2) extensive perivascular lymphocytic infiltration, (3) “burnt-out” forms of HIVE, and (4) β -amyloid ($A\beta$) accumulation with Alzheimer’s-like neuropathology. Chronic “burnt-out” forms of CNS infection could be a result of prolonged survival. Such cases are characterized by focal white matter pathology, nonspecific lesions with gliosis and neuronal atrophy (Gray et al., 2003) without overt inflammation and secondary infection. From the onset of the AIDS epidemic, several investigators recognized that HIV-1 involvement of the CNS associates with white matter gliosis and demyelination (Gray et al., 1991). Leukoencephalopathy might be one of the central manifestations of HIVE (Figure 22.1H), and its association with the development of HIV-1 neuro-cognitive disorders is often overlooked due to primary focus on neuronal injury. Increased frequency of HAD (Neuenburg et al., 2002) and in particular of a

highly destructive form of HIV-associated leukoencephalopathy (Langford et al., 2002) could be associated with the emergence of anti-retroviral drug-resistant forms of HIV-1. Severe leukoencephalopathy is characterized by significant perivascular infiltration of macrophages and lymphocytes, and it was assumed that this condition is due to an exaggerated response from a reconstituted immune system (Gray et al., 2003).

22.3.3. Patterns of Neuronal Injury

The neurodegenerative changes during HIV-1 infection are characterized by dendritic simplification of pyramidal neurons and selective loss of interneurons (Budka, 1991). The striato-cortical, cortico-cortical, and limbic intrinsic/inhibitory circuitries are mostly affected (Masliah et al., 1996). It is not clear whether they undergo neurodegeneration simultaneously or if there is a temporal progression of the neuronal injury from one site to another. Large pyramidal neurons in the neocortex (Wiley et al., 1991; Masliah et al., 1992), spiny neurons in the putamen (Masliah et al., 1996), medium-sized neurons in the globus pallidus, and interneurons in the hippocampus (Masliah et al., 1995) are among the most severely damaged neuronal populations. There was a 30–50% decrease in large neurons, accompanied by a 20% reduction in neocortical width in the frontal, parietal, and temporal cortices of brains with HIV (Gray et al., 1991; Asare et al., 1996). Both experimental animal models and studies of human brain tissues suggest that neuronal damage may start in synapses and dendrites and then spread to the rest of the neuron, thereby activating pathways leading to cell death via apoptosis (Garden et al., 2002). Moore and colleagues clearly established the association between markers of regional neurodegeneration (midfrontal cortex, hippocampus, and putamen) at autopsy and levels of neuro-cognitive impairment in HIV-1 infected patients (Moore et al., 2006). The regional combined scores based on the percentage of neuropil occupied by MAP-2 (marker of neuronal cell bodies and dendrites) and synaptophysin (SP, marker of synapses) better correlated with the level of global neuro-cognitive impairment than measures of neuronal markers individually. Regional combined scores for hippocampus and putamen were independent predictors of the degree of neuropsychological impairment before death. Combining information from several markers of neural injury provided the strongest association with degree of neuro-cognitive impairment during life.

22.4. Neuropathogenesis of HIV Infection

22.4.1. Mechanisms of Neuronal Injury During HIV-1 CNS Infection

It is now widely accepted that in the absence of viral infection of neurons or macroglia, indirect mechanisms play a major role in HAD neuronal dysfunction and death. Multiple studies per-

formed over the last decade and a half demonstrated that virus-infected microglia and macrophages secrete, or induce other neural cells to produce, neurotoxic factors that lead to neuronal injury or death during HIV. These neurotoxins include arachidonic acid and its metabolites (Nottet et al., 1995), platelet activating factor (Gelbard et al., 1994), pro-inflammatory cytokines [tumor necrosis factor (TNF- α) or interleukin-1 (IL-1 β)], quinolinic acid (Heyes et al., 1991), NTox (Giulian et al., 1996), nitric oxide (Adamson et al., 1996) and glutamate (Jiang et al., 2001). A significant reduction in toxin levels in CSF reversed neuro-cognitive impairment when anti-retroviral therapy was administered to a HAD patient (Gendelman et al., 1998). Neuronal damage and/or dysfunction can be caused by viral proteins such as gp120 (Brenneman et al., 1988), gp41 (Adamson et al., 1996) and Tat (New et al., 1997) secreted by infected brain macrophages. Virions released from macrophages bind to chemokine (chemotactic cytokines) receptors expressed on neurons (Hesselgesser et al., 1998; Zheng et al., 1999a).

In the past few years, significant progress was made in clarifying the biological importance of chemokines in the CNS. Initially viewed as immune modulators, chemokines appear to play much broader biological roles in the CNS including development, neuronal excitability and synaptic transmission, neuro-inflammation, and neurodegeneration. A number of α - and β -chemokine receptors are expressed on neurons, astrocytes, and microglia (Gabuzda et al., 1998; Ghorpade et al., 1998; Luster, 1998; Albright et al., 1999). Two of them, CXCR2 and CXCR4, were found in neuronal cells (Hesselgesser et al., 1998). CXCR4 plays a crucial role in receptor-mediated neuronal apoptosis and cell function (Hesselgesser et al., 1998; Zheng et al., 1999b). Since HIV-1 gp120 can bind to chemokine receptors initiating signal transduction (Weissman et al., 1997), the neuronal chemokine receptor expression and distribution on different types of neurons is significant for understanding of CNS homeostasis and HAD pathogenesis. CXCR4 expression was found on neurons positive for choline acetyltransferase (in the caudate putamen and substantia innominata) and tyrosine hydroxylase (in the substantia nigra pars compacta) (Banisadr et al., 2002). Stimulation of neuronal chemokine receptors, by virions, viral proteins or the CXCR4 natural ligand stromal derived factor-1 [SDF-1 α , upregulated in HIV (Zhang et al., 1998)] may alter intracellular signaling events, and cause neuronal dysfunction and apoptosis (Hesselgesser et al., 1998; Zheng et al., 1999a). Constitutive expression of CXCR4 on neurons suggests that HIV-1 gp120 or SDF-1 α could directly interfere with cholinergic and dopaminergic neurotransmission leading to neuronal dysfunction seen in HAD. There is an apparent disagreement between neurotoxic potential of CXCR4 tropic viruses in vitro models and HIV-1 isolates that exist in the brain of patients with HAD. Brain-derived viruses are macrophage tropic and principally use CCR5 for virus entry (Ghorpade et al., 1998). The presence of HIV-1 variants with increased CCR5 affinity

and reduced dependence on CCR5 and CD4 in the brains of some HIV-1 infected patients with CNS infection suggested that variants with increased CCR5 affinity may represent a pathogenic viral phenotype contributing to HIV-1 neurodegenerative manifestations (Gorry et al., 2002). This apparent paradox could be associated with the predominance of indirect mechanisms of neurotoxicity (secretory substances of virus-infected and activated MP) in HIV-1 neuropathogenesis.

Laboratory models assaying neuronal function have been developed to mimic neuronal injury during HAD and to link virus infection, MP activation, chemokine production, and neuronal demise. Establishment of connection between neuronal dysfunction with brain MP activation was made possible by placing viral and/or immune products onto neurons and measuring cell signaling events or through *ex vivo* electrophysiological tests on MP-treated brain slices. Supernatants derived from HIV-1-infected MP were applied to the rat hippocampal brain slices (the site of mammalian learning and memory) and neuronal long-term potentiation (LTP; a neural response linked closely to learning and memory) was assayed. The diminished levels of LTP were detected in brain slices treated with supernatants acquired from virus-infected and activated MP as compared to uninfected or/and non-stimulated cells (Xiong et al., 1999). Establishment of such systems allowed testing of effects of inflammatory stimuli relevant to the neuropathogenesis of HAD and development of potential treatment approaches. IL-8 could represent one of the potential perpetrators in HAD-associated neuronal demise since elevated levels of IL-8 were detected in the brain tissue (Xiong et al., 2003b). When IL-8 effects on LTP were studied in hippocampal slices (Xiong et al., 2003b), this chemokine decreased LTP, and this inhibition was mediated through CXCR2 activation, suggesting a direct effect of IL-8 on synaptic transmission. *In vitro* studies demonstrated that neurotoxic factors secreted by MP can induce toxicity either directly or indirectly through downstream effects at the N-methyl-D-aspartate-type glutamate receptor leading to apoptosis (Kaul et al., 2001; Xiong et al., 2003a). Quantitative assessment of neuronal injury caused by HIV-1 infected, activated macrophages could be performed in neurotoxicity assays. The determination of neuronal structural proteins [MAP-2 and neurofilaments (NF)] was shown to correlate with neuronal dysfunction and could be used as a read-out system for neuronal survival/injury by computer-based imaging system (Zheng et al., 2004).

22.4.2. Astrocytes

How a relatively small number of infected MP localized in particular areas of the brain can lead to widespread neuronal injury is also unclear. One possibility is that interactions between immune competent MP and astrocytes lead to an amplifica-

tion of toxic immune responses (Tornatore et al., 1991). Histopathological studies performed with human autopsy tissue showed that reactive astrogliosis, detected by glial fibrillary acidic protein (GFAP) staining, coincided with increased trafficking of activated macrophages and concomitant microglial activation (Persidsky et al., 1999). Neuropathological observations also document that intense astrogliosis and microglial activation is observed in areas of axonal and dendritic damage in HAD (Masliah et al., 1997).

There was consistent evidence that astrocytes become infected with HIV-1 although at low frequency as compared to brain MP. HIV-1 antigens and/or nucleic acid have been identified in astrocytes in brain autopsy tissue from both adult and pediatric AIDS cases (Tornatore et al., 1994; Ranki et al., 1995). In cell cultures, HIV-1 infection of astrocytes results in an initial productive but non-cytopathogenic infection that diminishes to a viral persistence or latent state (Messam and Major, 2000). The major barrier to HIV-1 infection of primary astrocytes appears to be at virus entry and that astrocytes have no intrinsic intracellular restriction to efficient HIV-1 replication (Canki et al., 2001). These cells can play a dual role, amplifying the effects of inflammation and mediating cellular damage as well as protecting the CNS. Cytokine/chemokine communications between MP and astrocytes and viral proteins produced by MP are involved in the balance of protective and destructive actions by these cells. HIV-1 transactivator protein Tat significantly increases astrocytic expression and release of monocyte chemo-attractant protein-1 (MCP-1), β -chemokine (Conant et al., 1998). Interactions between activated MP and astrocytes lead to significant up-regulation of β -chemokines promoting MP infiltration in HIV (Persidsky, 1999; Persidsky et al., 1999). Secretion of α -chemokines by astrocytes was documented due to pro-inflammatory substances secreted by activated lymphocytes in the setting of HIV (Poluektova et al., 2001). Pro-inflammatory cytokines (TNF- α , IL- β and IFN- γ) and quinolinic acid present in abundance during HAD are potent inducers of α - and β -chemokines by astrocytes (Guillemin et al., 2003). Astrocytes can suppress HIV-1 replication in monocyte-derived macrophages (MDM) via the production of soluble factors (Hori et al., 1999) and down-regulate secretion of pro-inflammatory factors by HIV-1 infected MP (Nottet et al., 1995). FasL is a molecule promoting apoptosis, and it was shown to be upregulated during HIV on astrocytes (Ghorpade et al., 2003). Brain extracts from HAD patients had significantly elevated FasL levels compared to HIV-1-seropositive patients and seronegative individuals, and this mechanism can promote neuronal death via Fas-FasL interactions.

Astrocytes directly participate in synaptic integration by releasing glutamate via an exocytosis-like process. This occurs after activation of the receptor CXCR4 by SDF-1 (Bezzi et al., 2001). Autocrine/paracrine TNF- α -dependent signaling leading to prostaglandin formation controls glutamate release and astrocyte communication. Derangement of astrocyte processes is seen when activated microglia enhance release of cytokines

in response to CXCR4 stimulation. Changed glial communication has direct neuropathological consequences because agents interfering with CXCR4-dependent astrocyte-microglia signaling prevent neuronal apoptosis induced by HIV-1 gp120. In addition to other functions, astrocytes are a significant component of the BBB ensuring maintenance of unique phenotypic properties of brain microvascular endothelial cells (BMVEC) (Persidsky, 1999) that are altered in HIVE (Dallasta et al., 1999). Clearly, the mechanism of HIV-1 associated brain injury is complex, probably involving multiple neurotoxic factors and pathways.

22.5. HIV-1 Neuroinvasion and Blood–Brain Barrier Compromise

22.5.1. Cellular Neuroinvasion and the BBB

Diffuse myelin pallor is a prominent feature of HIV-induced neuropathogenesis observed both at the early stage of HIV infection and also in HIVE (Gray et al., 1993). It has been shown that white matter changes are caused by alteration of the BBB. Structural and functional abnormalities in the microvasculature during HIV-1 CNS infection have been identified, including serum protein leak, alterations in capillary endothelial cells and basement membranes (Petito and Cash, 1992; Weis et al., 1996). There is a disruption of BBB characterized by decrease in staining for proteins of tight junctions (TJ, ZO-1, occludin and claudin-5) that ensure structural integrity of barrier. Dallasta and colleagues demonstrated significant TJ disruption (as indicated by diminished ZO-1 and occludin staining) in HIVE patients (Dallasta et al., 1999). This correlates with monocyte infiltration into the brain (Persidsky et al., 2006) and is accompanied by up-regulation of adhesion molecules on brain endothelium in HIVE (Nottet et al., 1996).

Originally proposed for visna virus (Peluso et al., 1985), monocyte-associated virus traffic rather than cell-free traffic became the prevailing mode for entry of HIV-1 (Persidsky and Gendelman, 2003). Monocytes are less able to replicate HIV-1 while circulating in the blood, but they can replicate virus upon entering tissues and become macrophages (Gendelman et al., 1988). It is likely that the monocytes being precursors to perivascular macrophages are infected outside the CNS and their traffic result in HIV CNS disease. Indeed, several investigators showed that virus-infected perivascular macrophages are immunophenotypically similar to a subset of blood monocytes (Williams et al., 2001). These blood monocytes expand during HIV infection and preferentially harbor virus, suggesting a strong likelihood of this subset being a vehicle for HIV-1. Phylogenetic analysis of HIV gp160 sequences in a patient with HAD demonstrates a close relationship to the sequences found in deep white matter, blood monocytes, and bone marrow among the tissues examined (Liu et al., 2000). Accumulating evidence suggested that a population of CD14+ monocytes expressing high levels of CD16 is a primary target of HIV-1

in blood (Ellery and Crowe, 2005). It was demonstrated that HIV proviral DNA is preferentially harbored in a minor population expressing CD14/CD16 (Shiramizu et al., 2005), and data obtained in an animal model (rhesus macaques infected with simian immunodeficient virus, SIV) confirmed that SIV DNA is consistently localized in a CD14^{low}CD16^{high} subset (Williams et al., 2001; Williams et al., 2005). CD16+ monocytes express high levels of CX3CR1 and undergo transendothelial migration in response to chemokine secreted by endothelial cells, fractalkine (Ancuta et al., 2003). Thus, this migratory property possibly makes these cells ideal candidates destined to traffic to the CNS. Importantly, virus-infected monocytes migrate more efficiently in response to relevant β -chemokine, MCP-1 (Persidsky et al., 2006).

Based upon a number of studies, the following scenario of BBB injury during HIVE was suggested: soluble factors and/or interactions with inflammatory cells upregulate adhesion molecules on BMVEC (Nottet et al., 1996; Persidsky et al., 1997), monocytes are activated in peripheral blood (Pulliam et al., 1997; Williams et al., 2001, 2005), attracted to the BBB by increased secretion of β -chemokines within the CNS (Conant et al., 1998; Persidsky, 1999), monocyte–endothelial interactions lead to BBB compromise (Persidsky et al., 2006), and monocyte passage into the CNS. The temporal correlation between BBB disruption and perivascular infiltration of monocytes/macrophages suggests that a part of neuronal injury caused by HIV infection might be initiated at the vasculature. The decrease of BBB compromise in patients treated with anti-retroviral therapy is accompanied by an amelioration of neurocognitive impairment (Avison et al., 2004).

22.5.2. Modeling the BBB

The need for reliable in vitro laboratory systems to study the mechanisms of cell trafficking into the brain is obvious. The difficulties in establishing such a system, however, abound given the physiological and anatomical complexities of the BBB (Abbott, 2005). Modeling systems must take into account the cellular, matrix, immune and physiologic components of this system. The capillaries that form the BBB express a diverse array of functional characteristics that permit the regulation of cell, protein, and macromolecule passage between blood and brain (Hawkins and Davis, 2005). These are all difficult to recapitulate in laboratory cell systems. Nevertheless, diverse BBB models have been developed and include: (1) monolayers of primary BMVEC; (2) co-cultures of astrocytes and endothelial cells derived from organs other than the brain; and (3) co-culture systems of astrocytes and BMVEC expressing TJ, high level of tightness and unique transport systems (Persidsky et al., 1997). These systems allow studies of monocyte migration, effects of viral proteins and inflammatory factors on BBB function (Persidsky et al., 2006; Kanmogne et al., 2007).

22.5.3. Adaptive Immunity

While HIV-1 enters the brain early following viral infection (Davis et al., 1992), detectable productive viral replication and brain macrophage infiltration occur years later and only in some infected people (Sacktor et al., 2002). Explanations are that the virus either re-seeds the brain or endogenous control mechanisms that inhibit HIV-1 breaks down. Such an apparently effective control of viral replication in the brain present over years appears to be mediated by acquired T cell immunity, via cytotoxic CD8+ lymphocytes, (CTLs) (Sethi et al., 1988; Sopper et al., 1998). CTLs provide the principal regulatory elements that control persistent viral production in the periphery as well as the CNS (Dalod et al., 1999; Schmitz et al., 1999). A strong association between HIVE and profound immunodeficiency led to the conclusion that a lack of effective T cell immune responses is associated with ongoing viral production in the brain. Nonetheless, it is likely even more complex, as not all patients with profound immunodeficiency develop HAD and not all HAD patients have significant lymphocyte depletion. In human brain tissue with HIVE, a positive correlation was found between HIV-1_{pol} and IP-10/CD14 (MP marker)/CXCR3 (lymphocyte marker), and between CD14 and CXCR3 mRNA expression reflecting an association between virus replication in MP and MP-mediated attraction of T cells (Poluektova et al., 2001). Neuropathological analyses revealed increased numbers of CD8+ lymphocytes within the neuropil next to virus-infected MP in HIVE brains as compared to brain tissue from seropositive patients without evidence of encephalitis (Figure 22.1I) (Potula et al., 2005). In this setting, the inflammatory cytokines and cytotoxic molecules (like granzyme B or perforin) released by these cells upon activation could contribute to the neurological sequelae of infection. Infiltrating CD8+ T cells may serve as a source of activation stimuli (such as IFN- γ or CD40L) for brain MP.

22.6. Animal Models

22.6.1. Simian Immunodeficiency Virus (SIV)

The SIV model reproduces HIV-1-associated CNS disease including neuropathology, BBB injury, cellular and humoral anti-viral immune responses, and neuro-cognitive abnormalities (Williams et al., 2001; Zink and Clements, 2002). The SIV macaque model allows studies of pathogenesis of lentivirus-induced neurological disease. Disease progression, as seen in SIV infection, demonstrates the same pattern as HIV-1 infection in humans (initial phase of viral replication, period of viral latency, the development of immunosuppression, and death). SIV-infected animals develop neurological symptoms and neuropathologic changes that are similar to those of humans with HIVE (Murray et al., 1992). The SIV model system was instrumental in current understanding of HIV-1 neuropathogenesis including early entrance of virus

in the CNS (Chakrabarti et al., 1991), important details on the role of brain MP (microglia, perivascular macrophages) as the vehicle and reservoir for virus replication in the CNS (Kitagawa et al., 1991; Williams et al., 2001), significance of peripheral immune responses in control of virus replication (Williams and Hickey, 2002), inflammatory responses associated with CD8+ lymphocyte infiltration (Marcondes et al., 2001; Burudi et al., 2002; Kim et al., 2004b), inflammatory cytokine profiles similar to ones seen in HIVE (Orandle et al., 2001), and selective replication of neurovirulent strains (Babas et al., 2006). Development of an accelerated model (a combination of neurovirulent molecular clone, immunosuppressive and neurovirulent virus swarm) featured two distinct periods of virus replication in the CNS: (1) parenchymal microglial activation and possibly macrophage infiltration at the period of acute infection with subsequent decline paralleling suppression of viral replication; (2) one month later, a resurgence in virus replication with an increase in macrophage/microglia activation (Zink and Clements, 2002). Similar to human studies (Potula et al., 2005), virus-specific CTLs were found in the brains of SIV-inoculated macaques (Kim et al., 2004b). These cells are capable of eliminating virus-infected macrophages and microglia *in vivo* and may be causally linked to immune activation. SIV infected macaques were used to link the effects of antiretroviral drugs on CNS viral replication, development of encephalitis and reversible neuronal injury (Williams et al., 2005).

22.6.2. Feline Immunodeficiency Virus

Another model system that offers opportunities for studies of HIV-1 neuropathogenesis is the feline immunodeficiency virus (FIV), a lentivirus inducing an AIDS-like disease in cats that includes severe neurological deficits. Cats infected with FIV initially experience an acute flu-like syndrome including low-grade fever and transient lymphadenopathy, followed by an extended asymptomatic period that culminates in severe immunodeficiency paralleling due to a progressive decline in circulating CD4+ T cells and a sustained increase in activated CD8+ (English et al., 1994). While like HIV-1, FIV infects monocyte-derived cells (Beebe et al., 1994). FIV also infects CD8+ T lymphocytes and B-lymphocytes (English et al., 1993) *in vivo*, featuring a much broader host cell range than the pattern of cell tropism displayed by HIV-1. Although most primary isolates of FIV may efficiently target both T-lymphocytes and monocytes, productive infection *in vivo* is largely restricted to FIV-infected T-lymphocytes. Although there are clear differences between the viral genome structures and cellular tropisms of FIV and HIV-1, the systemic and CNS diseases produced in their respective hosts are remarkably similar. Both viruses display a highly conserved tropism for the chemokine receptor, CXCR4 (Willett and Hosie, 1999), and rapidly penetrate the CNS with preferential infection of microglia and macrophages.

Soon after infection, FIV appears in the CNS inducing neurological deficits in some animals. Symptoms seen in these animals include enhanced aggression, increased cortical slow wave activity, abnormal brainstem-evoked potentials, delayed righting and pupillary reflexes, marked changes in sleep architecture, and deficits in cognitive-motor functions (Steigerwald et al., 1999). Similar to other lentiviruses, FIV neurotropism was demonstrated by virus detection in brain tissue and CSF of cats infected by either peripheral or intrathecal inoculation (Johnston and Power, 2002). Neuropathologic examination of FIV-infected cat brains demonstrates microglial nodules with very rare, multinucleated giant cells, gliosis, perivascular lymphocytic infiltrates and myelin pallor. (Hurtrel et al., 1992; Boche et al., 1996). A significant neuronal loss is a feature of FIV infection (Meeker et al., 1997). MRS demonstrated reduced levels in the concentrations of the neuronal marker, N-acetyl-aspartate (NAA) and the NAA/Cr ratio within the brains of FIV-infected cats (Power et al., 1998). FIV can infect a number of different brain cells in vitro including astrocytes (Dow et al., 1990), microglia (Dow et al., 1990; Hein et al., 2003), BMVEC (Steffan et al., 1994), and choroid plexus macrophages (Bragg et al., 2002).

22.6.3. Small Animal Models

The limitations of the primate or cat models of human HIV-1 CNS infection include the costs, special facility requirements, the necessity of using mixtures of viral strains (in order to develop reproducible CNS infection), and the relatively small numbers of animals studied that preclude meaningful statistical analyses. These obstacles have urged researchers to develop small animal models. Several rodent models were established including transgenic mice (expressing viral proteins or relevant inflammatory factors seen in HAD), mice infected primarily with murine retroviruses, or severe combined immunodeficient (SCID) mice inoculated intracerebrally with human HIV-1 infected macrophages and reconstituted with human peripheral blood lymphocytes (PBL).

22.6.3.1. Transgenic Mice

The role of HIV-1 gp120 CNS over expression was studied in transgenic mice in which expression of gp120 derived from CXCR4 tropic virus was placed under regulatory control of the murine GFAP promoter (Toggas et al., 1994). Reactive astrogliosis was prominent in transgenic mice showing high levels of gp120 expression. A 40% reduction in the number of large neurons was found in the neocortex. The loss of this neuronal subpopulation was combined with widespread neuronal dendritic vacuolation. Using the Morris water maze, D'Hooge et al. (1999) showed reduced escape latency and swimming velocity during the acquisition trials in 12-month-old gp120 animals. The spatial memory (retention) was diminished in probe trials in transgenic mice of this age. Cognitive abnor-

malities correlated with neuronal dysfunction (synaptic plasticity and excitatory postsynaptic potentials measured in CA1 neurons in hippocampal slices) from a gp120 transgenic mice study (Krucker et al., 1998).

HIV-1 Tat protein has neurotoxic effects on in vitro systems and it therefore was proposed to contribute to HIV-1-associated neurological syndromes. Kim and colleagues established and characterized a transgenic mouse model in which Tat expression was regulated by both the astrocyte-specific GFAP promoter and a doxycycline (Dox)-inducible promoter (Kim et al., 2003). Dox-dependent Tat expression occurred exclusively in astrocytes. Tat expression in the brain caused profound abnormalities including failure to thrive, hunched posture, tremor, ataxia, slow cognition and motor movement, seizures, and premature death. Structural abnormalities of the cerebellum and cortex, brain edema, astrogliosis, degeneration of neuronal dendrites, neuronal apoptosis, and infiltration of activated monocytes and T lymphocytes were shown in these animals. Leukocyte CNS infiltration paralleled overexpression of α - and β -chemokines in these mice (Kim et al., 2004a).

22.6.3.2. Murine Retroviruses

The murine leukemia viruses (MuLV) are retroviruses with significant genetic differences from lentiviruses (like HIV-1) that can induce neurodegenerative disease (spongiform encephalomyelopathy in the hindbrain and spinal cord) in mice (Nagra et al., 1992). Infection results in progressive hind limb paralysis and leukemia that develop within weeks to months after inoculation in susceptible mouse strains. Importantly, intensity and progression of the neurological disease are well correlated with viral replication and accumulation of viral proteins in CNS tissue. Significant differences exist between various viral strains and they are related to the different routes of inoculation, virus and perhaps mouse strain-dependent susceptibility of specific CNS cell types, and strain-dependent speed of disease progression (Nagra et al., 1993). Viral strains resulting in more severe CNS pathology replicate more efficiently and spread in the peripheral organs of mice (Czub et al., 1992). MuLV-infected mice demonstrate neuronal loss, neurotoxin production and behavioral abnormalities, and could be a tool for testing therapeutic agents. However, there are dissimilarities from HIVE and these include the significant genetic differences of MuLV from HIV-1, a lentivirus. In addition, the pathology of MuLV spongiform encephalomyelopathy is generally distinct from that of HIV encephalitis. Spongiform changes are unusual in HIVE and there is a predilection for HIV-1 to infect mononuclear phagocytes in the basal ganglia and white matter of the cerebral hemispheres, whereas there is a relative paucity of MuLV infection in these areas (mostly brainstem and spinal cord). HIV-1 primarily infects microglia and macrophages and to a lesser extent astrocytes; whereas, MuLV, depending on the strain, significantly infects endothelial cells, microglia, oligodendrocytes,

astrocytes, and neurons. HIV-1 infection of the CNS results in multinucleated giant cell formation; these types of cells have not been described in MuLV-induced CNS disease. Spongiform changes devoid of significant inflammatory infiltrate are similar to those found in spinal cords of HIV-1 infected patients with vacuolar myelopathy but they are different from the generally non-spongiform pathology of HIVE.

22.6.3.3. *Severe Combined Immune Deficient Mouse Model*

In order to overcome some of the drawbacks associated with other mouse models, a model of HIVE in SCID mice was developed by Tyor et al. (1993). Human peripheral blood mononuclear cells (PBMC) were injected into the brains of SCID mice as well as cell-free HIV-1 either simultaneously with the PBMC or a day after the PBMC. One to four weeks after injection of human MDM, multinucleated giant cells, some of which were HIV-1 p24-positive, were detected primarily in the area of the needle tract. Mice inoculated with virus only had no HIV detected. HIV strains used included HIV-1IIB (CXCR4), HIV-1BAL (CCR5), HIV-1MN (CXCR4), and human monocyte derived macrophages (MDM) infected with HIV-1ADA (CCR5) in vitro prior to inoculation. There was evidence that the human macrophages present in HIV-1 infected SCID brains are activated since they were positively stained for MHC class II antigen, TNF- α , and occasionally IL-1 (Tyor et al., 1993). In order to improve the reproducibility of HIVE in SCID mice, key steps for the model development (infection of highly purified human MDM in vitro, placement of equivalent numbers of cells into the same brain regions by stereotactic techniques, mouse brain sampling, quantitation of astrogliosis through use of computer image analysis on serial coronal sections) were standardized. Stereotactic placement of the inoculum in replicate experiments allowed delivery of equal amounts of human HIV-1 infected MDM to the same anatomical areas (basal ganglia and cortex) in each mouse (Persidsky et al., 1996). HIV-1-infected human MDM (placed into the putamen and cortex of SCID mice) remained viable for five weeks. Multinucleated giant cells were located in perivascular spaces. HIV-1 p24 antigen expression detected in 40–60% of inoculated cells in mouse brains was persistent. Human MDM were immune activated (as defined by HLA-DR, IL-1 β , IL-6 and TNF- α expression), and neuronal injury (apoptosis) developed after virus-infected MDM placement into mouse brain tissue. Neuro-inflammatory responses (including astrogliosis, microglial reaction and cytokine production) started at three days and peaked two weeks post-inoculation. Similar patterns of cytokine expression were found in human and mouse brains with HIVE. These included the upregulation of both human and mouse TNF- α , VCAM-1 (define), and E-selectin that correlated with the inflammatory reaction in brain tissue and decrease in neuronal dendritic density in MDM injected and contra-lateral hemispheres.

Subsequent experiments demonstrated that SCID mice inoculated with HIV-1-infected MDM in the basal ganglia/cortex showed neuronal dysfunction (detected by impaired LTP, an electrophysiologic response linked closely to learning and memory) and associated cognitive impairment (Zink et al., 2002). Alterations in neuronal physiology paralleled diminished expression of the neuronal synaptic marker (SP) and neuronal axonal marker (NF) assayed in the hippocampus of HIVE mice. By two weeks, HIVE mice expressed 3.8- and 2.6-fold less NF and SP than shams. These findings support the notion that HIV-1-infected and activated brain macrophages can cause neuronal damage at distant anatomic sites. Importantly, the findings confirmed the value of the model in exploring the physiological basis of HAD and development of new therapeutic approaches for its treatment.

Cellular reservoirs and anatomical sanctuary sites, such as the CNS, hamper HIV-1 treatment and allow HIV-1 to persist. To these ends, the SCID mouse model was modified to allow spread of HIV-1 infection between human MDM in mouse brain tissue behind an intact BBB. This model permitted comparative assessment of different anti-retroviral drugs by measurements of viral load and numbers of infected human macrophages (Limoges et al., 2000; Limoges et al., 2001). New drug delivery systems across the BBB and novel neuroprotective therapeutics are under investigation (Persidsky et al., 2001; Dou et al., 2003; Dou et al., 2005).

22.6.3.4. *NOD/SCID and Studies of Acquired Immune Responses*

What role impaired immune responses play in HIV-1 associated neurodegeneration and HAD pathogenesis is also under investigation (Poluektova et al., 2002). A pattern of human CD8 cells activation and CNS infiltration seen in HIVE was reproduced in response to HIV-1-infected human macrophages injected into the brain of mice reconstituted with autologous peripheral blood lymphocytes (Poluektova et al., 2002). HIV-1-infected MDM were injected into the basal ganglia after syngeneic immune reconstitution by human PBL to generate a human PBL-non-obese diabetic (NOD)/SCID HIVE mouse. Engrafted T lymphocytes produced HIV-1 gag- and HIV-1pol-specific CTLs against virus-infected brain MDM within one week. This was demonstrated by tetramer staining of human PBL in mouse spleens and by IFN- γ ELISPOT. CD8, granzyme B, HLA-DR, and CD45RO-reactive T cells migrated to and were in contact with human MDM in brain areas where infected macrophages were abundant. The numbers of productively infected MDM were markedly reduced (>85%) during two weeks of observation. However, the levels of granzyme-positive cells were significantly reduced and generated CTLs were not able to completely eliminate HIV-1-infected cells.

Elimination of infected macrophages in the lymphocyte reconstituted SCID mouse HIVE model was accompanied by diminished infiltration of CD8+ lymphocytes in the

brain. Despite decreased amounts of HIV-1 infected MDM and CD8+ lymphocytes, astrogliosis and microglial reaction persisted. Brain tissue of hu-PBL-NOD/SCID mice showed neuronal injury when compared to SCID mice inoculated with HIV-1 infected MDM only. Expression of neuronal markers was restored after cessation of neuro-inflammation. Mice developed viremia due to infection of circulating CD4+ lymphocytes, and virus-specific antibodies were detected by Western blot in serum. In summary, this model reproduces important features of HIV-1 CNS infection including development of virus-specific CTL, human lymphocyte migration across the BBB, elimination of HIV-1-infected MDM and neuro-inflammation.

Failure to eliminate HIV-1 infected macrophages by CTL in the brain may be due to presentation of HIV-1 antigen by tolerogenic antigen presenting cells (like macrophages) (Persidsky and Gendelman, 2003). A rate limiting enzyme of kynurenine pathway of tryptophan metabolism, indoleamine 2,3-dioxygenase (IDO) is up-regulated in virus-infected macrophages (Grant et al., 2000) and is implicated in the inhibition of antigen-specific T cell proliferation (Mellor et al., 2003). The idea that IDO inhibitor could affect the generation of CTL and clearance of virus-infected macrophages from the brain was tested in hu-PBL-NOD/SCID model. One week after MDM injection in the basal ganglia, animals treated with IDO inhibitor showed increased numbers of CD3+, CD8+ and IFN- γ -producing human T lymphocytes in peripheral blood compared to controls. At week two, mice treated with IDO inhibitor demonstrated a two-fold increase in CD8+ T lymphocytes in the areas of the brain containing HIV-1-infected MDM compared to untreated controls (Potula et al., 2005). By week three, mice exposed to IDO inhibitor showed 89% reduction in HIV-1-infected MDM in the brain as compared to controls. Thus, manipulation of immunosuppressive IDO activity in HIVE may enhance the generation of HIV-1 specific CTL leading to elimination of HIV-1 infected macrophages in brain and attenuation of neuronal injury.

The hu-PBL-NOD/SCID model allowed investigation of potential contributions of co-morbidity factors, like alcohol abuse, in the progression of HIV-1 CNS infection. HIVE hu-PBL-NOD/SCID mice chronically exposed to ethanol demonstrated increased levels of HIV-1 p24, ineffective elimination of HIV-1 infected macrophages by CTLs in the brain, enhanced microglial reaction and prominent BBB damage. These data proved that alcohol could be an exacerbating factor in HIVE (Potula et al., 2006). Understanding of the mechanisms underlying combined toxic effects of HIV-1 brain infection and excessive alcohol use will help to design neuro-protective strategies.

Summary

Studies performed over a period of two decades indicate that HIV-associated cognitive impairment is a chronic neuro-inflammatory condition. Virus productive infection of brain MP

is important, however, it alone cannot explain multi-faceted effects of HIV-1 on chronic immune activation within unique brain milieu. Recent advances in understanding of HIV-1 neuropathogenesis identified vulnerable neuronal populations, correlated their loss with cognitive performance and neuro-imaging studies, proved the role of peripheral immune responses in control of HIV-1 replication and chronic immune activation leading to neurodegeneration, underscored the importance of BBB injury, defined specific sub-population of monocytes associated with disease progression and effects of ART. Better understanding of HIV-1 neuropathogenesis guides development of therapeutic approaches that include efficient delivery of anti-retroviral therapy, neuroprotective and anti-inflammatory strategies, and improvement in acquired immunity.

Review Questions/Problems

1. Pathology HIV-1 encephalitis (HIVE) is characterized by

- a. accumulation of neutrophils in the neuropil
- b. presence of multinucleated giant cells
- c. HIV-1 inclusions in the nuclei
- d. decrease in number of astrocytes

2. Brain structures most affected by HIV-1 encephalitis are

- a. basal ganglia
- b. cerebellum
- c. frontal cortex
- d. brain stem
- e. all of the above

3. Causes of neuronal injury in HIV-1 CNS infection are

- a. effects of viral proteins (gp41, gp120)
- b. cytokines and chemokines
- c. glutamate
- d. anti-retroviral therapy
- e. all of the above
- f. a, b, and c only

4. Productively infected cells in HIV-1 CNS infection are

- a. neurons
- b. endothelial cells
- c. oligodendrocytes
- d. macrophages/microglia
- e. all of the above

5. Virus present in the brain tissues is

- a. CCR5-tropic
- b. CXCR4-tropic
- c. CX3CR-tropic
- d. none of the above
- e. all of the above

6. HIV-1 CNS infection is best described as

- a. acute lytic viral infection of neurons
- b. chronic viral infection of oligodendrocytes
- c. chronic neuro-inflammatory condition driven by macrophage infection
- d. acute lytic infection of astrocytes
- e. none of the above

7. HIV-1 brain infection in post-HAART era is characterized by

- a. aggressive forms with severe HIVE and white matter injury
- b. "burnt-out" forms of HIVE
- c. more extensive β -amyloid (A β) deposition
- d. more often occurrence of opportunistic infections
- e. a and d
- f. a, b, and c

8. Introduction of HAART resulted in more severe neurocognitive impairment in HIV-1 infected patients

- a. true
- b. false

9. Peripheral anti-viral immune responses control in measure HIV-1 CNS infection

- a. true
- b. false

10. Blood-brain barrier is injured in HIV-1 brain infection

- a. true
- b. false

HTLV-I/II

Kazunori Fugo, Christian W. Grant, and Steven Jacobson

Keywords CNS, CTL, CSF, HAM/TSP, HLA, HTLV-I, LTR, PBMC

23.1. Introduction

Human T-cell lymphotropic virus type-I (HTLV-I) is an exogenous human retrovirus that causes adult T cell leukemia (ATL) and a progressive neurological disorder, HTLV-I associated myelopathy/tropical spastic paraparesis (HAM/TSP).

Most HTLV-I infected individuals are asymptomatic carriers. However, 0.25 - 3% infected individuals will develop HAM/TSP. HTLV-I integrated proviral genome is approximately 9kb including *gag*, *pol* and *env* genes common to all cis-acting retroviruses. A cis-acting enhancer element has been detected within the *gag* gene of several avian retroviruses, including Rous sarcoma virus, Fujinami sarcoma virus, and the endogenous Rous-associated virus-0. A consensus enhancer core sequence, GTGGTTTG, is present in all of these viral genomes (citation: Arrigo S et al., Mol Cell Biol 1987). The above viral genes are flanked by long terminal repeat (LTR). Human T-cell lymphotropic virus type-II (HTLV-II) is also an exogenous human retrovirus. Although rare, HTLV-II infection is associated with a chronic encephalomyelopathy similar to that of classic HTLV-I-associated HAM/TSP. In 2005, two new primate retroviruses were identified, Human T-cell lymphotropic virus type-III (HTLV-III) and Human T-cell lymphotropic virus type-IV (HTLV-IV), among individuals who hunt, butcher, or keep monkeys or apes as pets in southern Cameroon. However, it is still unknown whether these viruses are pathogenic and can be transmitted among humans.

HAM/TSP is clinically characterized by paraparesis associated with spasticity in the lower extremities, mild peripheral sensory loss, muscle weakness, hyperreflexia, and urinary disturbance associated with preferential damage of the thoracic spinal cord. Most of the patients with HAM/TSP are seropositive for anti-HTLV-I antibodies.

HAM/TSP predominantly affects the thoracic spinal cord. There is degeneration of the lateral corticospinal tract as well

as of the spinocerebellar or spino thalamic tract of the lateral column. These lesions are associated with perivascular and parenchymal lymphocytic infiltration with the presence of foamy macrophages, proliferation of astrocytes, and fibrillary gliosis. There is widespread loss of myelin and axons, particularly in the corticospinal tracts. Damage is most severe in the middle to lower thoracic regions of the spinal cord.

Several immunologic abnormalities such as increased spontaneous lymphoproliferation, elevated anti-HTLV-I antibody titers in sera and CSF, increased cytokine production, and cellular immune responses have been observed in patients with HAM/TSP. These abnormalities are more often observed in patients with HAM/TSP compared to HTLV-I infected asymptomatic carriers. Moreover, it has been suggested that an autoimmune mechanism may also be involved in the pathogenesis of HAM/TSP. These evidences suggests that dysregulation in immune system may be associated with pathogenesis of HTLV-I associated neurologic diseases and may be responsible for local parenchymal ("by-stander") damage. This chapter will focus on the abnormality of cytokine expression in peripheral blood and CSF, CD4 + and CD8 + cell response to the HTLV-I, and NK cell activity in patients with HAM/TSP.

23.2. Structure and Gene Regulation of HTLV-I/II

HTLV-I integrated proviral genome is approximately 9kb including *gag*, *pol* and *env* genes. These genes encode the viral core proteins, reverse transcriptase and envelope proteins, respectively. The above viral genes are flanked by long terminal repeat (LTR). HTLV-I integrated proviral genome contains the unique region at 3' of *env* gene, which is called pX region. pX region encodes the regulatory proteins of HTLV, Tax and Rex (Figure 23.1).

The LTR consists of three regulatory regions, U3, R and U5. The U3 region is the element that regulates transcription of the provirus, mRNA termination and polyadenylation

FIGURE 23.1. Scheme of the HTLV-I genome. The HTLV-I proviral genome is 9032 base pairs long. It consists of gag, pol and env genes. The above viral genes are flanked by long terminal repeat (LTR). pX region encodes the regulatory proteins of HTLV, Tax and Rex and accessory proteins.

FIGURE 23.2. Scheme of transcriptional activation of the viral promoter by Tax and components of the CREB signaling pathway. U3 element of LTR contains three 21 base pair nucleotide repeats known as Tax-responsive elements (TRE), which are composed of a CRE-like core flanked by GC-rich sequences. Tax interacts with the cellular transcription factor cAMP-response element binding protein (CREB) dimer and stimulates its DNA-binding activity to the viral promoter at TRE. Together, the Tax-CREB complexes bound to the viral promoter recruit the co-activator proteins CREB-binding protein (CBP)/p300, and P/CAF, which activates transcription by histone acetylation/chromatin-remodeling.

signals. These consists of three imperfect 21-base pair nucleotide repeats called Tax responsive elements (TRE) that are necessary for transcriptional activation by the Tax protein.

Tax, a transcriptional activator of the viral genome (Sodroski et al., 1984; Fujisawa et al., 1985), is a 40-kDa phosphoprotein comprised of 353 amino acids. Tax protein is the trans-activator protein, which drives viral gene expression from TRE within U3 region of LTR. Tax also interacts with cellular transcription factors such as cAMP-response element binding protein

(CREB) and coactivator p300/CBP, serum-response factor (SRF) and nuclear factor-kappa B (NF- κ B) (Johnson et al., 2001) (Figure 23.2). These interactions between Tax and CREB or SRF are responsible for HTLV-I transactivation. It was documented that forkhead box P3 transcription factor p3 (Foxp3) protein, which is specifically expressed in regulatory CD4 + T cells (Tregs) and is required for their development and function, detected in the nucleus of CD4 + CD25 + T cells with immunoregulatory function, is down-regulated in CD4 + CD25 + T cells in patients with HAM/TSP compared to asymptomatic carrier and healthy donor (Yamano et al., 2005). Tax interaction with these factors may lead to immune dysregulations in patients with HAM/TSP.

Rex, a 27-kDa phosphoprotein, is a splicing suppressor of the viral transcripts (Kiyokawa et al., 1985; Seiki et al., 1985). The p27-Rex protein, encoded by the same pX mRNA in an alternate reading frame, accumulates and suppresses splicing of the viral transcripts.

23.3. Clinical Features and Epidemiology of HTLV-Associated Myelopathy and Tropical Spastic Paraparesis (HAM/TSP)

HTLV-I has tropism for T lymphocytes. HTLV-I is the causative agent for adult T-cell leukemia (ATL) and a progressive neurological disease known as HTLV-I associated myelopathy/tropical spastic paraparesis (HAM/TSP) (Gessain et al., 1985; Osame et al., 1986). According to the clinical and laboratory guidelines for the diagnosis of HAM/TSP (Osame, 1990), clinically, HAM/TSP is characterized by muscle weakness, hyperreflexia, spasticity in the lower extremities, and urinary disturbance associated with preferential damage of the thoracic spinal cord. HTLV-I has been also shown to be associated with several other inflammatory diseases, such as alveolitis, polymyositis, and arthritis, uveitis, and Sjogren syndrome. There are also less certain associations with chronic infective dermatitis, Behcet disease, pseudohypoparathyroidism, and systemic lupus erythematosus (Kubota et al., 2000). Another closely related virus, human T-cell lymphotropic virus type II (HTLV-II), has also been implicated in development of neurological disorders (Lehky et al., 1996; Silva et al., 2002; Orland et al., 2003). In 2005, the new primate retroviruses, Human T-cell lymphotropic virus type-III (HTLV-III) and Human T-cell lymphotropic virus type-IV (HTLV-IV) were identified among individuals who hunt, butcher, or keep monkeys or apes as pets in southern Cameroon (Calattini et al., 2005; Wolfe et al., 2005). However, it is still unknown whether these viruses are pathogenic and can be transmitted among humans.

It is estimated that approximately 10–20 million people worldwide are infected with HTLV-I (Poiesz et al., 1980; Edlich et al., 2003). Endemic areas of HTLV-I are in southern Japan, Central and West Africa, the Caribbean, Central and South America, the Middle East, Melanesia (Blattner and Gallo, 1985;

Gessain, 1996), and there are also smaller foci in the aboriginal populations of Australia, Papua New Guinea, and northern Japan. In Europe and North America, the virus is found chiefly in immigrants from these endemic areas and in some communities of intravenous drug users. Within the endemic areas, the seroprevalence varies from 1% to 20%. In contrast to the human immunodeficiency virus (HIV), the majority of infected persons remain asymptomatic and only 5% will develop HAM/TSP or ATL (Gessain et al., 1985; Osame et al., 1986).

HTLV-I is transmitted via three major routes: (i) transmission from mother to child through breast milk; (ii) transmission by sexual contact (mainly from male to female); (iii) transmission by way of infected blood through blood transfusion or contaminated needle usage. Although HTLV-I can infect a wide range of vertebrate cells in vitro (Trejo and Ratner, 2000), it has been thought to preferentially infect CD4 + T cells in vivo (Richardson et al., 1990). Therefore, CD4 + T cells have been considered an important component contributing to the inflammatory process in HAM/TSP. However, several studies have indicated that CD8 + T-cells were also infected with HTLV-I in vivo (Hanon et al., 2000b; Hanon et al., 2000a). The mechanisms through which HTLV-I causes HAM/TSP are not completely understood, although virus-host immune interactions have been suggested to play a role in the pathogenesis of the disorder.

Approximately 5% of HTLV-I infected individuals will develop HAM/TSP or ATL. However, there is no diagnostic tool for early detection or accurate assessment of disease state. Recently, protein profiling in serum from patients to distinguish between these two disease states has been reported by using mass spectrometry (Semmes et al., 2005). This technology may lead new diagnostic tools for HTLV-I infected individuals.

23.4. Pathophysiology in CNS

For HAM/TSP disease development, HTLV-I proviral load is an important factor. Recently, a real time quantitative polymerase chain reaction (PCR) assay (TaqMan) was developed

that allows HTLV-I proviral DNA to be measured in peripheral blood mononuclear cells (PBMCs). This assay was used to quantify the respective HTLV-I proviral DNA loads in HAM/TSP patients and asymptomatic carriers where a 16-fold increase in HTLV-I proviral load was observed in HAM/TSP patients compared to asymptomatic carriers (Nagai et al., 1998). Similar results have also been reported in patient cohorts from Jamaica (Manns et al., 1999). Yamano et al. (2002) reported that the HTLV-I tax mRNA load correlated with the HTLV-I proviral DNA load ex vivo, and the HTLV-I tax mRNA load also correlated with the disease severity in HAM/TSP patients (Figure 23.3). Collectively, these observations strongly suggest that a high proviral load plays an important role in the etiology of HAM/TSP. It has been hypothesized that a high HTLV-I proviral load results in higher viral antigen presentation that may drive expansion of antigen-specific T cells and subsequently these T cells are involved in the development of HAM/TSP. Such a model is presented in Figure 23.3. Most individuals infected with HTLV-I have been shown to mount strong CTL responses to viral antigens (Jacobson et al., 1990; Bangham, 2000). It is thought that this strong CTL response functions to protect against disease development by reducing the proviral load (Jeffery et al., 1999). However, this increase in proviral load that results in a marked increase in HTLV-I antigen-specific CTL expansion has also been suggested to contribute to a HTLV-I specific inflammatory process seen in HAM/TSP (Nagai et al., 1998; Jeffery et al., 1999).

Other determinants that are associated with increased risk of developing HAM/TSP are host genetic factors. Nagai et al. (1998) demonstrated higher HTLV-I proviral loads in asymptomatic carriers of families with HAM/TSP patients than those of unrelated asymptomatic carriers. It has been reported that a higher risk of developing HAM/TSP is associated with the human leukocyte antigen (HLA)-A*02-, HLA-Cw*08-, HLA-DR1 +, and tumor necrosis factor (TNF)-863A- (Usuku et al., 1988; Jeffery et al., 1999; Jeffery et al., 2000; Vine et al., 2002).

Histopathological observations have demonstrated that HAM/TSP predominantly affects the thoracic spinal cord

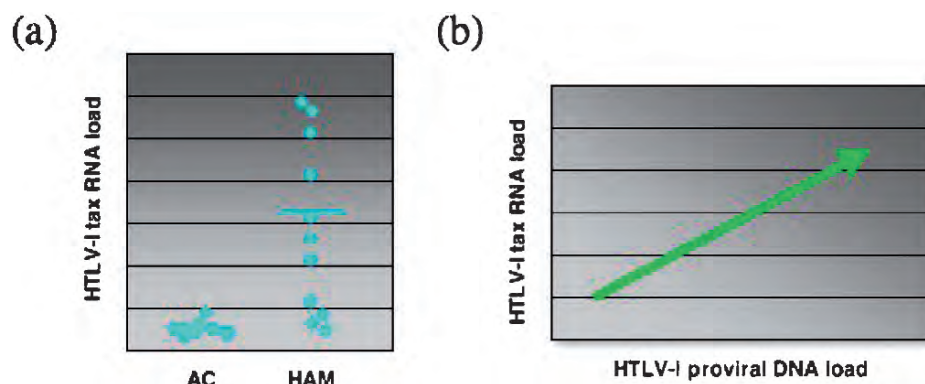

FIGURE 23.3. Schematic representation of the correlation between HTLV-I tax mRNA load in HAM/TSP patients and asymptomatic carriers. (b) Correlation between HTLV-I proviral load and HTLV-I tax mRNA load in HAM/TSP patients.

(Izumo et al., 1989; Levin and Jacobson, 1997). There is degeneration of the lateral corticospinal tract as well as of the spinocerebellar or spino thalamic tract of the lateral column. These lesions are associated with perivascular and parenchymal lymphocytic infiltration with the presence of foamy macrophages, proliferation of astrocytes, and fibrillary gliosis. There is widespread loss of myelin and axons, particularly in the corticospinal tracts of the spinal cord (Osame et al., 1986; Iwasaki, 1990; Umehara et al., 1993). Damage is most severe in the middle to lower thoracic regions of the spinal cord. The proximity to the areas containing inflammation, activation of macrophage/microglia, indicates that axonal damage is closely associated with inflammation in active-chronic lesions. Moreover, perivascular inflammatory infiltration was seen in the brain (deep white matter and in the marginal area of the cortex and white matter) of HAM/TSP patients, and the types of infiltrating cells were similar both in the spinal cords and brains (Aye et al., 2000). A nonrandom distribution of affected regions was suggested by autopsy studies, which showed the regions that are mainly affected are the so-called 'watershed' zones of the spinal cord in HAM/TSP patients (Izumo et al., 1992). This has partly been addressed by a magnetic resonance imaging study that showed increased abnormal-intensity lesions in the white matter of the brain of HAM/TSP patients (Kira et al., 1991). These results suggest that inflammatory changes occurred simultaneously in the spinal cord and in the brain, with the distribution of inflamed vessels closely correlated with the characteristic vascular architecture of the brain and the spinal cord, which led to a slowing of blood flow.

T-cell infiltrations in spinal cord lesions of HAM/TSP patients have been demonstrated by histopathological studies. The proportion of infiltrating cells shifted with the duration of the disease. HAM/TSP patients with short duration of illness, up to 5 years after onset, showed an even distribution of CD4 + T cells, CD8 + T cells, B cells, and foamy macrophages in damaged areas of the spinal cord parenchyma (Akizuki et al., 1989; Umehara et al., 1993). Immunohistochemistry showed that inflammatory cytokines such as TNF- α , IL-1 β , and interferon- γ (IFN- γ) were expressed on perivascular infiltrating macrophages, astrocytes, and microglia (Umehara et al., 1994a). HLA class I and beta2-microglobulin were expressed on endothelial cells and infiltrating mononuclear cells (Morgan et al., 1989; Wu et al., 1993). Up regulation of HLA class II expression was also found on endothelial cells, microglia, and infiltrating mononuclear cells in the affected lesions. In contrast, in patients with duration of illness from 8 to 10 years, there was a predominance of CD8 + T cells within spinal cord lesions with a concomitant down-regulation of proinflammatory cytokine expression, with the exception of IFN- γ (Umehara et al., 1993; Umehara et al., 1994a). Such lesions also express increased levels of HLA class I antigens from which HTLV-I specific CD8 + CTLs were isolated (Levin and Jacobson, 1997). Although many hematogenous macrophages could be found in the active-chronic lesions, markers of monocyte/macrophage recruitment and activation were down-regulated as the duration of illness progressed (Abe et al., 1999). These studies demonstrated that immune responses in the spinal cord lesions of HAM/TSP patients gradually change concomitantly with the duration of illness.

FIGURE 23.4. Schematic of induction of HTLV-I specific CD8+ T cells responses associated with immunopathogenesis of HAM/TSP. Quantitative PCR (DNA Taqman) demonstrates high HTLV-I proviral loads in HAM/TSP patients that are directly proportional to increased HTLV-I mRNA expression. In quantitative RT-PCR (RNA Taqman) analyses, elevated HTLV-I mRNA expression leads to increases of HTLV-I protein expression. This protein can be detected by flow cytometry. HTLV-I proteins (e.g., Tax) can be processed into immunodominant peptides such as Tax11–19 peptide and presented on the cell surface of infected cells in context with MHC class I molecules. HTLV-I Tax11–19 peptide strongly binds to HLA-A*0201 molecules and stimulates a virus-specific CD8+ T cells response. This Tax11–19/HLA-A*0201 complex can be detected with a TCR-like antibody, while the frequency of virus-specific CD8+ T cells can be determined by HLA-A*0201/Tax11–19 tetramers. These antigen-specific responses are expanded in the CSF of HAM/TSP patients and may contribute to disease progression by recognition of HTLV-I-processed antigens in the CNS associated with lysis of HTLV-I-infected inflammatory cells, HTLV-I-infected glial cells, and/or through induction of proinflammatory cytokines and chemokines.

Collectively, these histopathological studies suggested that an inflammatory process in the central nervous system (CNS) is involved in the pathogenesis of HAM/TSP.

CD8 + CTLs in the CNS of HAM/TSP patients was detected by immunohistochemical staining (Anderson et al., 1990; Umehara et al., 1994b). These studies support the hypothesis that HTLV-I infected CD4 + T lymphocytes enter the CNS which may drive local expansion of virus specific CD8 + CTLs. These virus-specific T cells may then either directly lyse virus infected cells and/or release a cascade of cytokines and chemokines that result in pathological changes (Figure 23.5). It is clearly important to define which cells might be targets of CTLs in the CNS.

HTLV-I Tax-specific CD8 + CTLs are hypothesized to play an important role in the development of HAM/TSP. Recently, through the development of tetramer technology, HTLV-I Tax-specific HLA-A*0201-restricted CD8 + T cells could be readily detected in HLA-A*0201 HAM/TSP patients (Altman et al., 1996; Greten et al., 1998). By using such tetramers, HTLV-I Tax 11–19-specific CD8 + cells from the PBMC of HLA-A*0201 HAM/TSP patients were found to represent an

extraordinarily high proportion of the total CD8 + population (Greten et al., 1998; Nagai et al., 2001b). Moreover, the frequency of these HTLV-I Tax11–19-specific CD8 + T cells was even higher in the CSF of HAM/TSP patients (Nagai et al., 2001c; Kubota et al., 2002). As we have shown that amount of antigen-specific cells are proportional to the amount of HTLV-I proviral DNA load and the levels of HTLV-I tax mRNA expression from PBMCs (Yamano et al., 2002), the increased frequency of HTLV-I Tax11–19-specific CD8 + T cells in HAM/TSP CSF suggest continuous HTLV-I antigen presentation in vivo (Figure 23.3).

However, it is unclear what cells express HTLV-I antigens in vivo since no HTLV-I protein can be readily detected in PBMCs from HAM/TSP patients ex vivo. This may be reconciled with the observations that virus-specific T cells recognize antigens by engaging the antigen-specific TCR with peptide/HLA complexes displayed on the surface of antigen presenting cells (APCs). While tetramers have been useful for monitoring virus-specific T cells, there has been a shortage of reagents to study and visualize the ligand for the TCR: the peptide/HLA complex (Cohen et al., 2003; Yamano et al., 2004).

FIGURE 23.5. Model of immunopathogenesis in HAM/TSP. HTLV-I infected CD4+ and CD8+ T cells, as well as antigen-specific T cells migrate across the blood brain barrier from the peripheral blood into the CNS. Recent studies have demonstrated that expression of Tax protein abrogates the regulatory function CD4+ CD25+ T cells by inhibiting expression of Foxp3 at the level of transcription. This event may promote an elevated level of T cell activation in patients with HAM/TSP. As a portion of these HTLV-I infected cells express HTLV-I antigens, antigen-specific T cells recognize antigen-expressing cells in the CNS. By recognition, HTLV-I specific CD8+ T cells can lyse infected target cells or produce proinflammatory chemokines and cytokines. Antibodies produced by B cells that are directed against viral proteins may also cross-react with cellular proteins, in a mechanism known as molecular mimicry. Cytokines such as IL-2 and IL-15 may help bystander T cells expansion. Neurotoxic cytokines such as IFN-gamma and TNF-alpha may contribute to the damage of resident glial cells and neurons in the CNS.

HTLV-I gag, pX, and pol sequences have been localized to the thoracic cord in areas with increased CD4 + cells infiltration using semiquantitative PCR (Akizuki et al., 1989; Yoshioka et al., 1993). The amount of HTLV-I DNA decreased concomitantly with the number of infiltrating CD4 + cells in the spinal cord lesions of HAM/TSP patients having a long duration of illness. HTLV-I DNA has been localized to inflammatory infiltrating UCHL-1 positive cells in affected spinal cord by in situ PCR technique (Matsuoka et al., 1998). HTLV-I tax mRNA was also detected in infiltrating CD4 + T lymphocytes in active lesions in CNS specimens from HAM/TSP patients using in situ hybridization (Moritoyo et al., 1996). In addition, the HTLV-I p19 protein has been localized to spinal cord lesions (Furukawa et al., 1994). Collectively, these findings suggest that the main reservoir of HTLV-I may be infiltrating CD4 + T lymphocytes. Other cells may also harbor the virus. HTLV-I RNA has been shown to localize to astrocytes (Lehky et al., 1995). Recent work using quantitative PCR (TaqMan) indicated that CD8 + T cells were also infected with HTLV-I in vivo (Nagai et al., 2001b). Using a sensitive flow cytometric technique, Hanon et al. also showed that in HTLV-I infection, a significant proportion of CD8 + T cells were infected with HTLV-I (Hanon et al., 2000a). Interestingly, a portion of HTLV-I specific CD8 + CTLs were also infected with HTLV-I and HTLV-I protein expression in infected CD8 + T cells rendered them susceptible to cytolysis mediated by autologous HTLV-I specific CD8 + CTLs (Hanon et al., 2000a). These findings indicate that HTLV-I specific CTLs may serve a dual function as both target and effector cells.

23.5. Immune Response to HTLV-I/II

Several immunologic abnormalities such as increased spontaneous lymphoproliferation, elevated anti-HTLV-I antibody titers in sera and CSF, increased cytokine production, and cellular immune responses have been observed in patients with HAM/TSP. These abnormalities are more often observed in patients with HAM/TSP compared to HTLV-I infected asymptomatic carriers.

The levels of the cytokines IFN- γ , TNF- α , and IL-6 were increased in the sera and CSF (Kuroda and Matsui, 1993). In peripheral blood lymphocytes (PBL) from HAM/TSP patients, mRNA for IL-1 β , IL-2, TNF- α , and IFN- γ are up-regulated (Tendler et al., 1991). Moreover, IL-2 and IFN- γ in PBMCs isolated from HAM/TSP patients was significantly elevated compared with both asymptomatic carriers and seronegative normal donors (Soldan, 2001). These data suggested that proinflammatory cytokines induced by Tax genes have been suggested to play a role in HAM/TSP pathogenesis.

NK cells are believed to protect against viral invasions at an early stage of an infection before the adaptive immune response is fully activated (Biron, 1997). Therefore, it is conceivable that impaired NK cell activity would result in

diminished control of viral infection and increase in viral replication of HTLV-I in HAM/TSP patients. NK cell activity has been reported to be significantly lower in HAM/TSP than in controls (Fujihara et al., 1991). In addition, NK cells from HAM/TSP patients have lower cytotoxic activity and lower antibody-dependent cell-mediated cytotoxicity than those from controls (Yu et al., 1991).

Human NK cell receptors are expressed by NK cells and also some T cells, primarily CD8 + CTLs (Mingari et al., 1998). Inhibitory NK cell receptors (iNKR) can down-regulate antigen-mediated T-cell effector functions, including cytotoxic activity and cytokine release (Mingari et al., 1998; Biassoni et al., 2001). It is reported that CD8 + T cells that express the NK cell inhibitory receptor were significantly decreased in HAM/TSP patients but not in asymptomatic HTLV-I carriers (Saito et al., 2003). These receptors are suggested to play a role in regulating CD8 + T cell-mediated antiviral immune responses; therefore, a decrease in their expression may result in higher risk of developing inflammatory diseases such as HAM/TSP.

Although HTLV-I can infect a wide range of vertebrate cells in vitro (Trejo and Ratner, 2000), CD4 + T cells are the main subset of cells infected with HTLV-I in vivo (Richardson et al., 1990). HAM/TSP patients have significantly higher frequencies of HTLV-I Env and Tax antigen specific CD4 + T cells as compared to HTLV-I infected asymptomatic carriers (Goon et al., 2002). It has been reported that CD4 + T cells in HAM/TSP patients have a more Th1-like phenotype as characterized by up-regulated secretion of proinflammatory cytokines such as IFN- γ and TNF- α and down-regulated levels of Th2 cytokines such as IL-4 (Horiuchi et al., 2000; Nakamura et al., 2000; Wu et al., 2000; Hanon et al., 2001). As suggested in the model presented in Figure 23.5, HTLV-I infected CD4 + T cells have increased adhesion activity to endothelial cells and transmigration activity through basement membrane that allows migration of infected CD4 + T cells into the CNS (Nakamura et al., 2000). Entry into the CNS by HTLV-I CD4 + T cells that have increased production of TNF- α , a neurotoxic cytokine, may be responsible for the initiation inflammatory processes seen in HAM/TSP.

One of the most striking features of the cellular immune response in HAM/TSP patients is the highly increased numbers of HTLV-I specific HLA class I restricted CD8 + CTLs in the PBL and CSF (Hinuma et al., 1981; Jacobson et al., 1990). Although HTLV-I CD8 + CTLs have been detected in PBMC of some asymptomatic carriers (Parker et al., 1992), the magnitude and frequency of these responses are higher in patients with neurologic disease (Elovaara et al., 1993). CD8 + CTLs recognize viral and other foreign antigens, usually as small 9-aa peptides, in the context of HLA class I alleles. Although HTLV-I Env, Pol, Rof and Tof (Pique et al., 2000) could be target proteins of HTLV-I specific CTLs, HTLV-I specific CD8 + CTL activity in PBL from HAM/TSP patients is typically restricted to p27x and p40x products of the HTLV-I tax gene (Elovaara et al., 1993). In particular, the

HTLV-I Tax11–9 peptide (LLFGYPVYV) has been defined as an immunodominant epitope presented in the context of HLA-A*0201 and can be recognized by CD8 + CTLs from HAM/TSP patients (Parker et al., 1992; Koenig et al., 1993). Tax11–19 conforms to a known HLA-A*0201 binding motif and has one of the highest affinities known for any peptide-HLA complex (Utz et al., 1992). Recently, HTLV-I Tax peptide loaded HLA-A*0201 dimers and tetramers were developed and used to demonstrate HTLV-I Tax-specific HLA-A*0201 restricted CD8 + T cells (Greten et al., 1998; Bieganska et al., 1999). HTLV-I Tax11–19-specific CD8 + cells from the PBMC of HLA-A*0201 HAM/TSP patients were found to represent an extraordinarily high proportion of the total CD8 + population (Greten et al., 1998; Nagai et al., 2001c). In patients with both HTLV-I Tax 11–19 and cytomegalovirus peptide-specific CD8+ T cells, only HTLV-I Tax 11–19 specific CD8+ cells are found to be elevated in the CSF as detected with tetramers (Nagai et al., 2001a; Kubota et al., 2002).

These studies suggest that the HTLV-I specific cells either are specifically expanded in the CSF or are recruited into the CNS from the periphery as depicted in Figure 23.2. Preferential expansion in the CSF may be associated with the recognition of HTLV-I infected cells in this compartment or in the CNS and thus may contribute to the neuropathology associated with HAM/TSP (Nagai et al., 2001a). Recently, it has been reported that HTLV-I tax mRNA expression levels in PBMCs correlated with the amount of HTLV-I Tax11–19-specific CD8+ T cells (Yamano et al., 2002) (Figure 23.4). These data suggest that HTLV-I specific CD8+ T cells may be continuously driven by HTLV-I antigen expression *in vivo*.

HAM/TSP patients have high proviral loads despite vigorous virus-specific CD8+ T cell responses; however, it is unknown whether these T cells are efficient in eliminating the virus *in vivo*. Sequencing analysis revealed that epitope mutations were remarkably increased in a patient when the frequency and the degeneracy of the HTLV-I specific CD8+ T cells were at the lowest. It was shown that the frequency and the degeneracy correlated with proviral load in the longitudinal study (Kubota et al., 2003).

The phenomenon of spontaneous lymphoproliferation, defined as the ability of PBMCs to proliferate *ex vivo* in the absence of exogenous antigens or stimulants such as IL-2, has been well described in PBLs from HAM/TSP patients, from HTLV-I asymptomatic carriers, and from HTLV-II infected persons (Kramer et al., 1989). However, the magnitude of this spontaneous lymphoproliferation is more pronounced in HAM/TSP patients than in asymptomatic HTLV-I carriers. The spontaneous lymphoproliferation of HTLV-I infected PBL is thought to consist of the proliferation of HTLV-I infected CD4+ cells and the expansion of CD8+ cells based on the demonstration of an increase in virus expressing cells concomitant with an increase in the percentage of CD8+ CD28+ lymphocytes. Experimentally, CD8+ T cells, including HTLV-I specific CD8+ T cells, have been shown to be expanded during spontaneous lymphoproliferation (Sakai et al., 2001).

The high frequency of HTLV-I specific CD8+ CTL in HAM/TSP patients correlates with the production of several cytokines. By intracellular cytokine staining coupled with flow cytometry, IFN-gamma, TNF-alpha, and IL-2 were all significantly elevated in the HTLV-I specific CD8+ cells of HAM/TSP patients compared with asymptomatic carriers and HTLV-I seronegative healthy controls (Kubota et al., 1998). In addition, HLA-A*0201 restricted HTLV-I Tax11–19-specific CD8+ CTL lines derived from a HAM/TSP patient released IFN-gamma and IL-2, with higher magnitude upon stimulation with Tax11–19 peptide (Nagai et al., 2001c).

It has been suggested that cytokine expression may be associated with an interaction of the TCR/Ag/HLA trimolecular complex. The molecular characterization of this trimolecular complex has led to major advances in the understanding of how the immune response recognizes antigen and has resulted in technologies that use these MHC-peptide complexes to directly visualize antigen-specific T cells (Greten et al., 1998). HTLV-I Tax11–19-specific CD8+ cells have been shown to possess cytolytic activity directed towards cells expressing HTLV-I Tax peptide via a perforin-dependent mechanism. Increased production of a of MMP-9, chemoattractants (macrophage inflammatory proteins 1alpha and 1beta), and proinflammatory cytokines (TNF-alpha and IFN-gamma) as a result of CD8+ T cell receptor mediated activation by HTLV-I antigens can contribute to damage of CNS tissues (Biddison et al., 1997; Greten et al., 1998; Kubota et al., 1998; Lim et al., 2000).

Moreover, it is documented that an autoimmune mechanism may also be involved in the pathogenesis of HAM/TSP (Levin et al., 1998; Levin et al., 2002b; Levin et al., 2002a; Jernigan et al., 2003). A unique T-cell receptor CDR3 motif, which has been demonstrated in brain lesions of MS and in the animal model experimental autoimmune encephalomyelitis, was also detected in infiltrating lymphocytes in the spinal cord of HAM/TSP patients (Hara et al., 1994). Furthermore, Levin et al. (1998) have provided new evidence in support of molecular mimicry as a possible mechanism in HAM/TSP pathogenesis. Serum immunoglobulin from HAM/TSP patients reacted to neurons in HTLV-I uninfected human CNS but not to cells in the peripheral nervous system or other organs. This reactivity was abrogated by pretreatment with recombinant HTLV-I tax protein. IgG from brain, CSF, and serum of the HAM/TSP patients showed immunoreactivity with heterogeneous nuclear ribonuclear protein-A1 (hnRNP-A1) as the autoantigen. This antibody specifically stained human Betz cells, and infusion of autoantibodies in brain sections inhibited neuronal firing (Levin et al., 2002b; Levin et al., 2002a; Jernigan et al., 2003). These data suggest that molecular mimicry between HTLV-I and autoantigens in CNS might play a role in the pathogenesis of HAM/TSP.

These evidences suggests that dysregulation in immune system may be associated with pathogenesis of HTLV-I associated neurologic diseases and may be responsible for local parenchymal ("by-stander") damage.

23.6. Animal Models of HTLV-I/II Infection

HTLV-I can be consistently infected into rabbits, rats and squirrel monkeys (Lairmore et al., 2005). HTLV-I infectivity for rabbits was first reported by using intravenous inoculations of the MT-2 cell line (Akagi et al., 1985), a T-cell leukemia cell line established from a patient with ATL, and with the Ra-1 cell line (Miyoshi et al., 1985), a rabbit lymphocyte cell line derived from cocultivation of rabbit lymphocytes with MT-2 cells. The rabbit model has provided important information regarding the immune response against HTLV-1 infection (Cockerell et al., 1990). Establishment of a rabbit model of clinical HTLV-1 disease has been more problematic. In the majority of studies, rabbit infection has paralleled the asymptomatic infection of humans. Sporadic clinical lymphoproliferative disorders in HTLV-1-infected rabbits were reported (Simpson et al., 1996; Kindt et al., 2000; Zhao et al., 2002). In each of these cases, clinical disease developed after one year and usually several years after the initial infection.

Rats have been infected with HTLV-1-producing cells and offer a tractable model of HAM/TSP, the neurologic disease associated with the viral infection (Suga et al., 1991; Sun et al., 1999; Hakata et al., 2001). Wistar-King-Aptekman-Hokudai (WKAH) rats emerged as a model of HAM/TSP. HTLV-1-infected WKAH rats develop spastic paraparesis with degenerative thoracic spinal cord and peripheral nerve lesions several months following inoculation (Ishiguro et al., 1992; Kushida et al., 1993). The pathology of rat HAM/TSP differs from that seen in humans. Lesions in humans have a marked T-cell infiltration of affected regions, whereas lymphocytes are not seen in the lesions in rats (Yoshiki, 1995). Subsequent studies defined the time periods over which the pathologic changes occur and indicated that apoptosis of oligodendrocytes and Schwann cells is the primary event leading to demyelination (Yoshiki, 1995; Yoshiki et al., 1997; Ohya et al., 2000). Macrophages are seen in the lesions of rats in response to the demyelination. Production of HTLV-1 pX mRNA, tumor necrosis factor (TNF) alpha mRNA, as well as altered expression of the apoptosis-modifying genes, bcl-2, bax, and p53, have been identified within the lesions (Ohya et al., 2000; Tomaru et al., 2003). In addition, HTLV-1 provirus has been identified in microglial cells and macrophages associated with lesions (Kasai et al., 1999).

Development of rat models for clinical ATL has required the use of immunodeficient rats. Ohashi et al. (1999) demonstrated that an 'ATL-like lymphoproliferative disease' could be established in adult nude (nu/nu) rats following inoculation of some HTLV-1-immortalized cell lines. This led to studies that examined methods of protection against tumor development, including adoptive transfer of T cells (Kannagi et al., 2000) and Tax-specific peptide vaccines (Hanabuchi et al., 2001).

The squirrel monkey has been successfully infected with HTLV-1 and offers an attractive non-human primate model of HTLV-1 for vaccine testing (Kazanji et al., 2000; Kazanji

et al., 2001; Mortreux et al., 2001; Sundaram et al., 2004). In this model, peripheral lymphocytes, spleen, and lymph nodes were verified as major reservoirs for HTLV-1 virus during the early phase of infection (Kazanji et al., 1997; Kazanji et al., 2000). It was subsequently established that similar to humans, HTLV-1 infection in squirrel monkeys begins through reverse transcription of the virus genome, which is then followed by clonal expansion of infected cells (Mortreux et al., 2001).

HTLV-I infected mouse models would be useful in providing a small and inexpensive animal for studies of pathogenesis, treatment, and prevention of ATL or other HTLV-I related diseases. However, HTLV-1 does not efficiently infect murine cells. Thus, mouse models must be manipulated to establish HTLV-1 infection.

Transgenic models of HTLV-1 have provided an understanding of the role of Tax and Tax-mediated disruption of lymphocyte function or cytokines in HTLV-1-associated lesions. Arthropathy and other autoimmune diseases developed in Tax transgenic mice and rats controlled through the HTLV-1 promoter (Iwakura et al., 1991; Iwakura et al., 1995; Yamazaki et al., 1997). Transgenic animals expressing Tax manifested mammary adenomas or carcinomas (Yamada et al., 1995; Hall et al., 1998). Overall, these studies showed the strong support that Tax has the oncogenic capabilities, although they did not demonstrate mechanisms of carcinogenesis. Recently, Hasegawa et al. (2006) reported generating HTLV-I tax transgenic mice using the lck proximal promoter. The founder and offspring developed diffuse large cell lymphomas that are histologically similar to ATL cells. Further analysis is expected. Bovine leukemia virus (BLV) infection of sheep offers a reliable model of disease associated with delta retrovirus infections and insight into viral genetic determinants of tumor induction (Willems et al., 2000).

Summary

HTLV-I virus-host immune interactions play a pivotal role in HAM/TSP. HTLV-I has a unique pX region in the genome that might lead to immune dysregulation in patients with the disease. High HTLV-I proviral loads in both CD4+ and CD8+ T cell populations drive increased HTLV-I mRNA levels that result in increased HTLV-I protein expression. Processing of HTLV-I proteins and presentation of HTLV-I specific peptides leads to activation and expansion of antigen-specific T cell responses. The hypothesis that HTLV-I specific CD8+ CTLs play a role in the development of HAM/TSP is supported by localization of these CTL in the CNS. HTLV-I specific CD8+ cells could recognize productively infected cells and respond either by direct lysis of the infected cell or through the release of proinflammatory cytokines and chemokines. These molecules can act to recruit and expand additional inflammatory cells, and have been shown to be toxic to CNS tissue. Several studies suggest that HTLV-I infected lymphocytes may preferentially migrate into the

CSF from peripheral blood or that HTLV-I infected lymphocytes may selectively expand in this compartment. This process is illustrated in Figure 23.5. It is reported that HTLV-I genomic sequences, RNA, and protein have been localized to spinal cord lesions. Therefore, all requirements for CTL recognition, including viral antigen and HLA class I expression, are present in the HAM/TSP lesion, lending support to the argument that CD8+ CTL may be immunopathogenic in this disease. Intensive studies regarding the interaction between HTLV-I specific CD8+ T cells and HTLV-I infected cells will clarify the pathogenesis of HAM/TSP.

Review Questions/Problems

1. Which is most unusual symptom in patients with HAM/TSP?
 - a. spastic paralysis
 - b. higher brain dysfunction
 - c. bladder and rectal disturbance
2. Which antibody is detected in patients with HAM/TSP?
 - a. anti HTLV-I antibody
 - b. anti HIV-I antibody
 - c. anti ganglioside antibody
3. Which inflammatory disease is shown to be associated with HTLV-I infection?
 - a. gastritis
 - b. myelitis
 - c. uvelitis
4. Which level of spinal cord is predominantly affected in patients with HAM/TSP?
 - a. cervical level
 - b. thoracic level
 - c. lumbar level
5. Which cells are infiltrated in the chronic phase of HAM/TSP?
 - a. CD4 positive T cells
 - b. CD8 positive T cells
 - c. B cells
6. Which circulated cytokine is up-regulated in patients with HAM/TSP?
 - a. IL-2
 - b. IL-4
 - c. IL-10
7. Which part is mostly degenerated in spinal cord in patients with HAM/TSP?
 - a. Anterior column
 - b. Lateral column
 - c. Posterior column
8. Which is most endemic area of HTLV-I?
 - a. North America
 - b. Caribbean
 - c. Europe
9. What type of human leukocyte antigen (HLA) is regarded as the higher risk factor associated with HAM/TSP?
 - a. HLA-A*02(+)
 - b. HLA-Cw*08(+)
 - c. HLA-DRB1*0101(+)
10. Which cytokine is mostly detected at degenerated spinal cord in HAM/TSP?
 - a. TNF-alpha
 - b. IL-1 beta
 - c. IFN-gamma
11. Which is characteristically detected in T cells of patients with HAM/TSP?
 - a. Spontaneous lymphoproliferation
 - b. Down-regulation of the ratio of CD4/CD8
 - c. Eruption of the "flower cells"
12. How much is the frequency of the development of HAM/TSP in HTLV-I carrier?
 - a. Less than 5%
 - b. 10% to 20%
 - c. More than 50%
13. Which is inappropriate infection route of the HTLV-I?
 - a. Transmission through breast milk
 - b. Sexual contact
 - c. Droplet infection
14. Which adhesion molecules are mostly detected in the spinal cord of HAM/TSP?
 - a. ICAM-1
 - b. VCAM-1
 - c. ICAM-1 and VCAM-1
15. Which part is histopathologically affected in spinal cord of HAM/TSP?
 - a. Axon
 - b. Myelin
 - c. Axon and Myelin
16. Which inflammatory disease is shown to be associated with HAM/TSP?
 - a. Sjogren syndrome
 - b. Atopic dermatitis
 - c. Crohn's disease
17. Which is predictive finding in regard to CSF of HAM/TSP patients?
 - a. Leukocyte: Normal range to slightly increasing, Sugar: Normal range

- b. Leukocyte: Moderate increasing, Sugar: Normal range
- c. Leukocyte: Moderate to severe increasing, Sugar: Decreasing

18. Which sex is much developed in HAM/TSP?

- a. Male
- b. Female
- c. No difference between male and female

19. What are the reservoir cells of the infected HTLV-I?

- a. T cells
- b. B cells
- c. Macrophages

20. Which is strongly associated with the development of HAM/TSP?

- a. Leukocyte increasing
- b. Hypercalcemia
- c. High proviral load

Viral Encephalitis

Clinton Jones and Eric M. Scholar

Keywords Encephalitis; Herpes simplex virus type 1; Varicella zoster virus; Cytomegalovirus; West Nile virus; Acyclovir; Valacyclovir; Ganciclovir; Cidofovir; Fanciclovir; Foscarnet; Latencyneurological disorders; Lifecycle

24.1. Introduction

Encephalitis is an acute inflammation of the brain that is caused by a viral infection. Several viruses, herpes simplex virus type 1 (HSV-1), Varicella zoster virus (VZV), cytomegalovirus (CMV), West Nile virus, and certain members of the Flavivirus family or Bunyavirus genus for example, can cause encephalitis. Although these viruses have very different biological properties, they have the ability to enter the central nervous system, replicated in neurons, and can all cause encephalitis. In general, patients with encephalitis suffer from fever, headache, seizures, and photophobia. Less commonly, stiffness of the neck can occur with rare cases of patients also suffering from stiffness of the limbs, slowness in movement and clumsiness depending on which part of the brain is involved. Encephalitis is not a typical outcome of viral infections, but it is life threatening and difficult to treat. This chapter discusses the properties of the viruses that cause encephalitis, how they cause clinical disease, and the available therapeutic strategies that are available.

24.2. Herpes Simplex Virus-Mediated Encephalitis (HSE)

24.2.1. Summary of Herpes Simplex Virus Type 1 Productive Infection

Herpes simplex virus type 1 (HSV-1) is a double-stranded DNA virus that has a genome size of 152 Kb, and it encodes at least 84 proteins. Binding and entry of HSV-1 into permissive cells is mediated by viral proteins binding to cellular

receptors (Spear, 1993). After uncoating, the viral genome is present in the nucleus and viral gene expression ensues. HSV gene expression is temporally regulated in three distinct phases: immediate early (IE), early (E), or late (L) (Honess and Roizman, 1974). IE gene expression does not require protein synthesis and is stimulated by VP16 (O'Hare, 1993). In general, proteins encoded by IE genes regulate viral gene expression, and as such are important for productive infection. E gene expression is dependent on at least one IE protein, and generally E genes encode nonstructural proteins that play a role in viral DNA synthesis. L gene expression is maximal after viral DNA replication, requires IE protein production, and L proteins comprise the virion particle.

24.2.2. Summary of Latent Infection

Acute infection is typically initiated in the mucosal epithelium, and then HSV-1 establishes latency in sensory neurons located in trigeminal ganglia (TG) or sacral dorsal root ganglia. Despite a vigorous immune response during acute infection, latency is established. As many as 20–30% of sensory neurons are latently infected (reviewed in Jones, 1998, 2003). As a consequence of primary infection, HSV-1 genomic DNA is also present in the central nervous system (CNS) of a significant proportion of the adult human population (Fraser et al., 1981).

The latency associated transcript (LAT) is abundantly transcribed in latently infected neurons (reviewed in Jones, 1998, 2003). Mice, rabbits, or humans latently infected with HSV-1 express LAT. In productively infected cells or latently infected rabbits, an 8.3-Kb transcript is expressed that has the same sense as LAT. Splicing of the 8.3-Kb transcript yields an abundant 2-Kb LAT and an unstable 6.3-Kb LAT. The majority of LAT is not capped, is poly A-, appears to be circular, and is designated as a stable intron. In small animal models, LAT is important but not required for the latency-reactivation cycle (reviewed in Jones, 1998, 2003). The first 1.5 Kb of LAT coding sequences are important for reactivation from latency. It is not clear whether LAT encodes a protein or is a regulatory RNA.

LAT interferes with apoptosis in transiently transfected cells and in TG of infected rabbits or mice (Jones, 2003). Inhibiting apoptosis may be the most important function of LAT because two anti-apoptosis genes, the bovine herpesvirus 1 (BHV-1) LAT homologue (Mott et al., 2003; Perng et al., 2002) and the baculovirus IAP gene (Jin et al., 2005), can restore levels of spontaneous reactivation to a LAT null mutant.

24.2.3. Epidemiology of Herpes Simplex Viruses

Approximately 90% of the population is infected with herpes simplex virus type 1 (HSV-1), and at least 10% with HSV-2 (Nahmias and Roizman, 1973; Whitley, 1997). Humans are the only natural reservoir for this infection, and no vectors are involved in transmission of this virus (Stanberry et al., 2004). HSV-1 primary infection occurs mainly in childhood, and HSV-2 infection occurs predominantly in sexually active adolescents and young adults. Aerosols or close contact are the primary mechanisms of viral transmission. Although transmitted by different routes and involving different parts of the body, these two viral subtypes have similar epidemiology and clinical manifestation.

24.2.4. Pathogenesis of HSE

HSV is the most commonly identified cause of acute, sporadic viral encephalitis in the United States, accounting for 10–20% of all cases (Corey, 2005). It is estimated that there are about 2.3 cases per million individuals per year. There are peaks at 5–30 years of age and at more than 50 years of age. Since the 1940s, HSV-1 and HSV-2 have been implicated in the causation of acute necrotizing encephalitis in infants, children, and adults. Encephalitis due to HSV-2 in newborn infants is a widespread disease in the brain and commonly involves a variety of other organs in the body, including the skin, eyes, and lungs (Stanberry et al., 2004).

HSE is characterized by severe destruction of temporal and frontal lobe structures, including limbic mesocortices, amygdala, and hippocampus. Without antiviral therapy, the mortality rate is as high as 70%; but even after antiviral therapy 20% of these patients die. Despite early treatment, chronic progressive tissue damage in magnetic resonance imaging (MRI) can be found up to 6 months following the onset of symptoms. Approximately 2/3 of the HSE cases occur because of reactivation from latency (Yamada et al., 2002), which explains why there is high morbidity and long-term complications despite antiviral treatment (Lahat et al. 1999; McGrath et al., 1997; Skoldenberg, 1991).

In general, HSE is associated with necrotic cell death resulting from virus replication and inflammatory changes secondary to virus-induced immune response (DeBiasi et al., 2002). However, there is not a perfect correlation between virus burden in the brain and the severity of histological changes and neurological symptoms. Furthermore, a small number of HSE patients are negative for HSV-1 DNA early in

the course of infection, suggesting that factors other than virus replication are involved in cell death/disease pathogenesis.

24.2.5. Animal Models for Studying HSE

HSE occurs in a certain percentage of mice or rabbits following infection. The frequency of HSE in experimental infections is dependent on the pathogenic potential of the HSV-1 and the mouse strain used for experimental infection. For HSE to occur after ocular infection, the virus must enter the TG, and then spread to the CNS, or the virus directly gains access into the brain via the optic nerve. Models have also been developed in which the virus is directly inoculated into the brain. In this model, transport from the peripheral tissue → the peripheral nervous system → the CNS is not important. Thus, viral genes necessary for neuronal transport and spread are not crucial for virus infection if the brain is inoculated.

Viral genes necessary for productive infection, inhibiting apoptosis, or inhibiting immune recognition would likely play a significant role in the potential of HSV-1 to initiate encephalitis. Innate immune responses play a significant role in lethal encephalitis because HSV-1 interactions with Toll-like receptor 2 contribute to HSE (Kurt-Jones et al., 2004). A recent study has demonstrated that LAT enhances the frequency of encephalitis in male Balb/C mice (Jones et al., 2005). Thus, viral- and host-specific factors regulate the frequency of HSE.

24.2.6. Clinical Features of HSE

Two recognizable groups of symptoms are seen in most patients. First of all there are nonspecific symptoms that are seen in most forms of encephalitis, including fever, headache, and signs of meningeal irritation such as nausea, vomiting, confusion, generalized seizures, and alteration of consciousness. The second group of changes is referable to focal necrosis of the orbitofrontal and temporal cortices and the limbic system, and includes anosmia, memory loss, peculiar behavior, speech defects, hallucinations (particularly olfactory and gustatory), and focal seizures. There is rapid progression in some cases, with the appearance of reflex asymmetry, focal paralysis, hemiparesis and coma. Cerebral edema contributes to these symptoms and plays an important role in the outcome (Stanberry et al., 2004).

24.2.7. Therapy

A number of nucleoside analogs are active against primary and recurrent HSV infection. Acyclovir is the major therapy used for HSV encephalitis. It should be given intravenously at a dose of 10 mg/kg every 8 h for 14–21 days. It is usually well tolerated with few side effects. Valacyclovir and famciclovir are alternative drugs used for the treatment of HSV encephalitis (Griffiths, 1995; Stanberry et al., 2002, 2004). For a description of these drugs see §5.

24.3. Varicella Zoster Virus (VZV)-Induced Encephalitis

24.3.1. Summary of Virus Lifecycle and Virus Transmission

Humans are the only known reservoir for VZV, and VZV is a ubiquitous human pathogen. Like HSV-1, VZV is a large double stranded DNA virus that encodes at least 70 different genes. VZV contains many genes that are similar to HSV-1, suggesting they are functional homologues. Thus, the general steps during productive infection are similar for VZV and HSV-1 and will not be discussed in detail here.

24.3.2. Latency of VZV

VZV appears to be latent only in ganglia, and viral genomes are primarily found in sensory neurons. Analysis of latent VZV is restricted to human ganglia obtained at autopsy. Based on *in situ* hybridization (ISH) studies combined with sequencing, four transcripts corresponding to VZV genes 21, 29, 62, and 63 have been identified in latently infected human ganglia. A monospecific polyclonal antiserum directed against VZV ORF 63 protein detected this protein in the cytoplasm of neurons (reviewed in Mitchell et al., 2003). These VZV proteins are primarily in the nucleus during productive infection (zoster), suggesting that the cytoplasmic location might maintain VZV in a latent state.

24.3.3. Epidemiology of VZV

A serologic study of 1201 U.S. military trainees indicated that 95.8% had been exposed to virus (Jerant et al., 1998). Chickenpox is common in childhood and affects both genders equally as well as people of all races. VZV is spread by droplet or airborne transmission and is highly contagious. The primary infection is seen as varicella (chickenpox), a contagious and usually benign illness that occurs in epidemics among susceptible children. The VZV virus is highly contagious and can be contacted by aerosol, human contact, or coughing. Primary infection produces varicella (chickenpox), after which VZV becomes latent in neurons of cranial nerve, dorsal root, and autonomic ganglia along the entire neuro-axis. Reactivation from latency can occur decades later, resulting in zoster (shingles), which tends to be more localized than the chickenpox infection.

24.3.4. Clinical Features of VZV

Acute VZV infection leads to chickenpox, which is characterized by malaise, fever, and an extensive vesicular rash (Abendorth and Arvin, 2000). Chickenpox in the immunocompetent child is mostly benign and associated with lassitude and a temperature of 100–103°F for 1–2 days. Other symptoms include malaise, itching, anorexia, weakness, and exhaustion, and these gradually resolve as the illness improves. The hallmark of chickenpox is the skin manifesta-

tions that consist of maculopapules, vesicles, and scabs in varying stages. In general immunocompromised children have more numerous lesions. Although chickenpox is usually a mild disease, there are exceptions to this rule. For example, an epidemic of 292 cases of chickenpox occurred in rural India resulted in 3 deaths (Balraj and John, 1994). In the United Kingdom about 25 people die from chickenpox every year, in part because VZV vaccination is not mandatory (Rawson et al., 2001). VZV vaccine effectively prevents varicella; however, breakthrough varicella and virus reactivation can still occur (reviewed by Arvin and Gershon, 1996).

With chickenpox the most frequent organ affected other than the skin is the CNS (Liesegang, 1999). The neurologic abnormalities are often seen as acute cerebellar ataxia or encephalitis. Encephalitis is the most serious complication of chickenpox, and it can be life threatening in adults. It occurs in 0.1–0.2% of patients with chickenpox (Johnson and Milbourn, 1970).

Herpes zoster is characterized by a unilateral vesicular eruption with a dermatome distribution. Postherpetic neuralgia (pain that persists more than 30 days after the onset of rash after cutaneous healing) is the most serious complication in immunocompetent patients. The incidence and duration of postherpetic neuralgia are directly correlated with the age of the patient. Acute retinal necrosis caused by varicella-zoster virus occurs occasionally in immunocompetent patients although more recent reports have focused on ocular disease in HIV-infected patients. In HIV-infected patients the lesions rapidly increase in size and coalesce. These lesions respond poorly to antiviral therapy and almost inevitably cause blindness in the involved eye. The retinitis is less aggressive in immunocompetent patients and can often be treated with antiviral therapy such as acyclovir. Neurologic complications associated with zoster are diverse, including motor neuropathies of the cranial and peripheral nervous system, encephalitis, meningoencephalitis, myelitis, and Guillain-Barré syndrome (Liesegang, 1999). Extracutaneous sites of involvement include the CNS, as shown by meningoencephalitis or encephalitis. The clinical symptoms are similar to those of other viral infections of the brain. This involvement of the CNS with cutaneous herpes zoster is probably more common than recognized clinically. Classically, VZV infection involves dorsal root ganglia. Motor paralysis can occur as a consequence of the involvement of the anterior horn cells, in a manner similar to that encountered with polio. These patients may have severe pain. Herpes zoster in the immunocompromised patient is more severe than in the normal person, but even in these patients disseminated herpes zoster is rarely fatal.

24.3.5. Neurological Disorders Associated with VZV

In general, neurological diseases occur as a result of reactivation from latency. The neurological complications after VZV reactivation are serious and can be life-threatening. VZV is the

causal agent in 29% of 3231 cases of encephalitis, meningitis, and myelitis, and VZV is the most common cause of encephalitis in patients over age 65 (Rantalaaho et al., 2001). More than 500,000 Americans develop zoster (severe dermatomal distribution pain and rash) every year. Zoster is frequently followed by postherpetic neuralgia (pain that persists for months and often years after the rash disappears), myelitis, or unifocal or multifocal vasculopathy. Many cases of VZV vasculopathy, myelitis, and polyneuropathy occur in the absence of rash. Since VZV causes a wide spectrum of neurological disorders, testing for VZV DNA and antibody in cerebrospinal fluid (CSF) should be routinely performed. Proper diagnosis is critical because antiviral treatment can be curative, even after weeks to months of chronic VZV infection.

Subsequent reactivation of latent VZV in dorsal root ganglia results in a localized cutaneous eruption termed “herpes zoster” (or shingles). The epidemiology of herpes zoster differs from that of chickenpox. Decreasing virus-specific cell-mediated immune responses, which occur naturally as a result of aging or that result from immunosuppressive illness or medical treatments, increases the risk of shingles (Gnann and Whitley, 2002). Herpes zoster occurs in persons who are seropositive for VZV or more specifically in those who have had chickenpox. Most patients who develop herpes zoster have no history of exposure to other persons with VZV infection at the time of the appearance of lesions. Over 90% of adults in the U.S. have serologic evidence of varicella-zoster infection and are at risk for herpes zoster. The annual incidence is about 1.5–3.0 cases per 1000. Zoster occurs during the lifetime of 10–20% of all persons (Liesegang, 1999). Increasing age is a key risk factor for the development of herpes zoster. The other major risk for herpes zoster is altered cell-mediated immunity. Patients with cancer, those receiving immunosuppressive agents, and organ-transplant recipients are thus at increased risk of shingles. Persons who are positive for human immunodeficiency virus also develop herpes zoster at a higher frequency than those who are negative (Liesegang, 1999).

24.3.6. Potential Models to Study VZV Neuropathogenesis

Unlike HSV-1, VZV does not reactivate from ganglia after experimental infection of primates or rodents. However, after footpad inoculation of rats with VZV, the protein encoded by gene 63 can be detected in lumbar ganglia 1 month after infection. Viral protein is also detected in neurons, both in the nuclei and cytoplasm of infected cells. An independent study using the same rat model detected VZV gene 63 DNA in 5–10% of neurons and VZV RNA in neurons and non-neuronal cells (Kennedy et al., 1999). Simian varicella virus may also be a valuable model to study the pathogenesis of varicella virus–host interactions. Finally, the application of humanized immunodeficient mice (SCID-hu) to VZV has provided new information

about viral genes that are necessary for viral growth and pathogenesis (Ku et al., 2005).

24.3.7. Therapy

Therapy for herpes zoster should be aimed at accelerating healing, limiting the severity and duration of acute and chronic pain and reducing any complications associated with the infection. In patients who are immunocompromised, therapy should also be aimed at reducing the risk of viral dissemination. Acyclovir, valacyclovir, and famciclovir are all used in the United States for the treatment of herpes zoster. Acyclovir is approved in the U.S. for the treatment of both chickenpox and herpes zoster in the normal host. Oral acyclovir therapy in normal children, adolescents, and adults shortens the duration of lesion formation by about a day, reduces the total number of new lesions by about 25%, and reduces many of the symptoms in about a third of patients (Gnann and Whitley, 2002; Snoeck et al., 1999).

24.4. Human Cytomegalovirus (CMV)-Induced Encephalitis

24.4.1. Summary of Virus Lifecycle

Human cytomegalovirus (HCMV) is a β -herpesvirus that is an important causative agent of congenital disease and is a significant opportunistic infection (Knipe and Howley, 2001). HCMV is the largest member of the human herpesvirus group. It is estimated to encode at least 165 genes. In contrast to HSV-1, HCMV exhibits a highly restricted host range in cell culture. Primary differentiated fibroblasts show the greatest susceptibility to infection. As with other herpes–viruses, the HCMV-immediate early genes regulate viral transcription and inhibit cellular responses to infection (apoptosis and interferon induction, for example).

24.4.2. Epidemiology of HCMV

CMV is widely distributed among humans—from developed, industrial societies to isolated aboriginal groups (Pass, 1995). As with the other herpesviruses, CMV is readily contracted. The prevalence of CMV increases with age in every group that has been studied. In general, prevalence is greater and acquired earlier in life in developing countries and in the lower socioeconomic sections of developed countries. Infection rates are higher in nonwhites, but these racial differences appear to reflect differences associated with socioeconomic status and living conditions (Pass, 2001).

24.4.3. Pathogenesis and Persistence of HCMV

In healthy individuals, primary infection is usually subclinical, leading to persistence of the virus in a latent state throughout

the lifetime of the host. However, primary infection of newborns and reactivation from latent infections in immunocompromised individuals can lead to systemic and chronic disease. Unlike HSV-1 and VZV, HCMV does not typically establish latency in the nervous system. Myeloid-lineage hematopoietic cells (e.g., granulocytes, macrophages, and dendritic cells) are important targets for lifelong latency. HCMV latent gene expression is localized to the immediate early 1 (IE1) and IE2 regions. These transcripts appear to originate from both strands, but it is not clear if IE1 and IE2 proteins are expressed. Since these proteins are known to promote productive infection, high levels of expression do not appear to be consistent with latency. Several open reading frames also exist on the antisense strand of the latency associated transcripts. Antibodies to these ORFs are recognized by serum from healthy seropositive individuals, suggesting they are expressed during natural infection (Kondo et al., 1996).

With respect to HCMV causing disease in immune-suppressed individuals, reactivation from latency appears to be more important than primary infection. It is believed that cytokine-induced differentiation of latently infected cells can lead to a cell type that supports productive infection (Hahn et al., 1998), and viral amplification results from reduced immune surveillance (Fiala et al., 1973). Like many persistent/latent viral infections, the early events associated with reactivation from latency are poorly understood.

24.4.4. Clinical Features of HCMV

Although HCMV-induced clinical conditions are usually asymptomatic in patients with intact immune systems, it is a common opportunistic pathogen in immunocompromised patients. In HIV-infected persons CMV disease appears to be due to reactivation of the latent virus in a previously infected host. The clinical manifestations of CMV disease are generally seen when the CD4 T-lymphocyte count falls below 100 cells/ml. Retinitis is perhaps the most well known disease associated with this infection. Other features associated with this infection include gastrointestinal disease, pneumonitis (in the bone marrow transplantation patients), and neurologic disease. HCMV is associated with various neurologic infections in HIV-positive people, particularly inflammation of the ventricle accompanied by encephalitis (ventriculoencephalitis) and ascending polyradiculopathy (disease or injury involving multiple nerve roots). Ventriculoencephalitis usually occurs in advanced HIV infection in persons with a prior CMV diagnosis. Polyradiculopathy is the most common CNS infection caused by CMV and is characterized by urinary retention and progressive bilateral leg weakness. The clinical symptoms generally progress over several weeks to include loss of bowel and bladder control and paralysis. A spastic myelopathy has been reported and sacral paresthesias may occur. The CSF often shows a greater than normal number of cells, a less than normal content of glucose, and elevated protein levels (Cheeseman, 2004; Cheung and Teich, 1999).

24.4.5. HCMV-Induced Encephalitis

Approximately, two out of three newborn children that have symptomatic congenital CMV infection have CNS involvement (Bopanna et al., 1992). The CNS pathology includes microcephaly, elevation of cerebrospinal fluid protein, and neurologic abnormalities (poor feeding, lethargy, or generalized hypotonia, for example). Cranial computed tomography (CT) scans are abnormal in 75% of symptomatic newborns, with the most common abnormality being periventricular calcification (Bopanna et al., 1997). Fortunately, only 5–10% of newborns with congenital HCMV infection are symptomatic.

24.4.6. Treatment

Although antiviral agents currently available for CMV are not ideal, their use has decreased the burden of this disease in transplant patients and has improved the quality of life and survival of patients infected with this virus. Three antiviral agents have been shown to be effective in CMV disease and have been approved for use in the U.S. They are ganciclovir, foscarnet and cidofovir (Cheeseman, 2004; Cheung and Teich, 1999). Antiviral therapy for esophagitis, enterocolitis, endophthalmitis, peripheral neuropathy, polyradiculoneuropathy, and pneumonitis is usually with intravenous ganciclovir or foscarnet regimens similar to those used for retinitis. Patients with CNS or neurologic disease often respond best to combination therapy (Arribas et al., 1996).

24.5. Therapeutic Agents Available to Treat Herpes Viruses

24.5.1. Acyclovir

Acyclovir (Figure 24.1) is an acyclic guanine nucleoside analog that lacks a 3'-hydroxyl on the side chain. It has good antiviral activity against all herpesviruses and is widely used in the treatment of several different herpesvirus infections. Acyclovir was the first drug clearly demonstrated to be effective against herpes simplex virus infections (Wagstaff et al., 1994).

Acyclovir selectively inhibits viral DNA synthesis. It is preferentially activated in virally infected cells. Cellular uptake and initial phosphorylation are facilitated by the herpes virus thymidine kinase. The affinity of acyclovir for HSV

FIGURE 24.1. Acyclovir.

thymidine kinase is about 200-fold greater than for the mammalian enzyme. Cellular enzymes then subsequently convert the monophosphate to acyclovir triphosphate. Acyclovir triphosphate is present in 40- to 100-fold higher concentrations in HSV-infected than in uninfected cells, and competes for endogenous deoxyguanosine triphosphate. The triphosphate competitively inhibits viral DNA polymerases to a much greater extent than cellular DNA polymerases. The triphosphate is also incorporated into viral DNA, where it acts as a chain terminator as a result of the lack of the 3'-hydroxyl group. The terminated DNA template containing acyclovir binds the enzyme and leads to irreversible inactivation of the DNA polymerase (Scholar and Pratt, 2000; Wagstaff and Bryson, 1994).

The oral bioavailability of acyclovir is poor and ranges from 10–30%. The drug is poorly protein bound but is widely distributed throughout body fluids and tissues, including the cerebrovascular fluid. It is primarily excreted unchanged in the urine (Wagstaff et al., 1994).

Acyclovir is useful for treating infections caused by HSV, herpes zoster, and for VZV infections (Whitley and Roizman, 2001). Although HCMV is relatively resistant to acyclovir, some cytomegalovirus infections have responded marginally to large doses of acyclovir, and it seems to be effective for the prophylaxis of cytomegalovirus infections in immunocompromised patients. Epstein-Barr virus is not sensitive to acyclovir, and clinical infections do not respond to the drug.

Oral acyclovir is recommended for the treatment of varicella infection (chickenpox) in patients over 13 years of age who are otherwise healthy, children over 12 months of age with a chronic cutaneous or pulmonary condition or receiving long-term salicylate therapy, and in children receiving short or intermittent courses of aerosolized corticosteroids. Intravenous acyclovir should be used for treatment of varicella infection in immunocompromised children, including those receiving high doses of corticosteroids. Acyclovir has been shown to be the most effective agent for the treatment of infections caused by VZV (Snoeck et al., 1999).

Parenteral acyclovir is the drug of choice for the treatment of initial and recurrent mucosal or cutaneous herpes simplex infections in immunocompromised patients and for the treatment of disseminated, neonatal, encephalitic, and severe first episodes of genital herpes simplex infections in immunocompetent patients (Whitley, 1997). Intravenous acyclovir should also be used for severe diseases such as encephalitis (Brady and Bernstein, 2004).

Acyclovir is generally well tolerated whether administered topically, orally, or by the intravenous route. GI disturbances, headache, and rash may occur. Renal dysfunction due to crystalline nephropathy is more likely with IV administration, rapid infusion, in patients in the dehydrated state and with underlying renal disease, and in large doses. CNS effects are rare but include encephalopathy, tremors, hallucinations, seizures, and coma. Due to an elevated pH, intravenous administration may also cause phlebitis and inflammation at sites of extravasation (Wagstaff et al., 1994).

24.5.2. Valacyclovir

Valacyclovir is an ester prodrug of acyclovir. It provides significantly better oral bioavailability compared to acyclovir. This advantage results in substantially higher serum acyclovir concentrations than is possible with oral acyclovir. In addition, fewer daily doses are required with valacyclovir (Curran and Noble, 2001).

After oral administration and absorption, valacyclovir is converted to acyclovir, which is the active antiviral component of valacyclovir. The antiviral activity and mechanism of action of valacyclovir is identical to that of acyclovir (Perry and Faulds, 1996). The oral bioavailability of valacyclovir is significantly greater than that of acyclovir. Oral administration of valacyclovir results in plasma acyclovir concentrations comparable to those observed with intravenous acyclovir.

Valacyclovir is indicated for the treatment of herpes zoster (shingles), for the treatment of initial and recurrent episodes of genital herpes, and for the suppression of recurrent genital herpes in immunocompetent and HIV-infected patients. It is also indicated for the reduction of transmission of genital herpes in immunocompetent individuals, and for the treatment of cold sores. Valacyclovir appears to be equally effective in treating herpes zoster and recurrent genital herpes in immunocompetent adults. Valacyclovir has shown efficacy in the prophylaxis of cytomegalovirus infections in transplant patients (Perry and Faulds, 1996).

Like acyclovir, valacyclovir is a well-tolerated drug. The most common adverse effects of valacyclovir are headache and nausea. Other adverse events associated with valacyclovir administration include vomiting, weakness, dizziness, and abdominal pain. Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome has also been reported in a few patients after high doses of valacyclovir, as has confusion, hallucinations, and nephrotoxicity (Curran and Noble, 2001; Perry and Faulds, 1996).

24.5.3. Famciclovir

Famciclovir (Figure 24.2) is an oral prodrug of the antiviral agent penciclovir. Famciclovir lacks intrinsic antiviral activity, and this drug owes its activity to formation of penciclovir. Penciclovir is an acyclic guanine nucleoside analog. Penciclovir and its prodrug famciclovir are chemically similar to acyclovir. Penciclovir differs structurally from acyclovir only by the presence of an additional hydroxyl group. Famciclovir is the diacetyl 6-deoxy

FIGURE 24.2. Famciclovir.

analog of penciclovir. The mechanism of antiviral activity of penciclovir is also similar to that of acyclovir. Both drugs inhibit viral DNA synthesis (Scholar and Pratt, 2000). Penciclovir is rapidly and selectively phosphorylated in virus-infected cells by viral thymidine kinase to the monophosphate, and this is followed by further phosphorylation to the triphosphate, which is the active form of the drug. Over 90% of penciclovir triphosphate in virus cells is the (S)-enantiomer, a competitive inhibitor of DNA polymerases with respect to the natural substrate deoxyguanosine triphosphate (dGTP). Inhibition of the polymerase results in prevention of viral replication by inhibition of viral DNA synthesis. The R enantiomer of penciclovir triphosphate has only minimal activity on viral DNA polymerases (Scholar and Pratt, 2000). In contrast to acyclovir triphosphate, which is an obligate DNA chain terminator, penciclovir triphosphate allows DNA chain extension owing to its free hydroxyl group; however, penciclovir appears at least as effective as acyclovir as an inhibitor of herpes virus DNA synthesis.

Famciclovir is rapidly converted to penciclovir in intestinal and liver tissue after oral administration. More than half of an oral dose of famciclovir is excreted in the urine as unchanged penciclovir. The plasma elimination half-life of penciclovir is about 2 h, similar to that of acyclovir; however, the intracellular half-life of penciclovir in herpes virus-infected cells is considerably longer than that of acyclovir.

Oral famciclovir is used for the treatment of immunocompetent patients with herpes zoster infections and for the treatment and suppression of recurrent genital HSV. It is also indicated for the treatment of recurrent mucocutaneous herpes simplex in both immunocompetent and immunocompromised patients. Famciclovir is fairly well tolerated. Adverse effects include headache, dizziness, nausea, and diarrhea (Scholar and Pratt, 2000).

24.5.4. Ganciclovir

Ganciclovir is an acyclic guanine nucleotide analog with a structure similar to acyclovir but with an additional hydroxymethyl group on the acyclic side chain. It is inhibitory to all herpes viruses but is especially active against cytomegalovirus.

Like acyclovir and penciclovir, ganciclovir inhibits viral DNA synthesis. Also like these other agents, it is first phosphorylated intracellularly by the virus-induced enzyme to the monophosphate form. Further phosphorylation to the di- and triphosphates is catalyzed by cellular enzymes. Intracellular ganciclovir triphosphate concentrations are tenfold higher than those of acyclovir triphosphate and decrease much more slowly with an intracellular half-life of elimination greater than 24 h. These differences probably explain at least in part the greater activity of ganciclovir against cytomegalovirus and provide a rationale for single daily doses in suppressing human cytomegalovirus infections (Markham and Faulds, 1994; Scholar and Pratt, 2000). Ganciclovir triphosphate acts as an inhibitor and substrate for cytomegalovirus DNA polymerase. Ganciclovir triphosphate competitively inhibits the binding

of deoxyguanosine triphosphate to DNA polymerase, which results in the inhibition of DNA synthesis and termination of DNA elongation. Ganciclovir is incorporated into both viral and cellular DNA. It appears to limit viral DNA synthesis and the packaging of viral DNA into infectious units.

The bioavailability of orally administered ganciclovir is quite low. In patients with normal renal function the plasma half-life is about 2–4 h. Concentrations of ganciclovir in cerebrospinal fluid are lower than those in serum after intravenous administration (Markham and Faulds, 1994). More than 90% of the drug is eliminated unchanged in the urine. The plasma half-life increases as creatinine clearance declines and may reach 28–40 h in patients with severe renal insufficiency. Ganciclovir is an effective antiviral agent for the treatment of serious life-threatening or sight-threatening cytomegalovirus (CMV) infections in immunocompromised patients. Intravenous ganciclovir, foscarnet, or the combination of both are recommended for the treatment of cytomegalovirus neurological syndromes (Markham and Faulds, 1994).

The dose-limiting and most common adverse effect with intravenous and oral ganciclovir is bone marrow suppression (anemia, leukopenia, neutropenia, and thrombocytopenia). These effects are usually reversible upon withdrawal of the drug. CNS side effects are less common and range in severity from headache to behavioral changes to convulsions and coma. Fever, edema, phlebitis, disorientation, nausea, anorexia, rash, and myalgias have also been reported with ganciclovir therapy (Markham and Faulds, 1994).

24.5.5. Foscarnet

Foscarnet (Figure 24.3) is an inorganic pyrophosphate analog that has antiviral activity against all herpes viruses and the human immunodeficiency virus. Foscarnet is a pyrophosphate analog that acts as a noncompetitive inhibitor of many viral RNA and DNA polymerases as well as HIV reverse transcriptase (Chrisp and Clissold, 1991). It is approximately a 100-fold greater inhibitor of herpes virus DNA polymerase than the cellular DNA polymerase- α ; however, some human cell growth suppression has been observed with high concentrations in vitro. Inhibition of DNA polymerase results in inhibition of pyrophosphate exchange, which prevents elongation of the DNA chain (Scholar and Pratt, 2000). Similar to ganciclovir, foscarnet is a virostatic agent. Foscarnet is not a nucleoside and thus not phosphorylated. It reversibly blocks the pyrophosphate-binding site of the viral polymerase in a noncompetitive manner and inhibits cleavage of pyrophosphate from deoxynucleotide triphosphates.

FIGURE 24.3. Foscarnet.

The oral bioavailability of foscarnet is poor, so intravenous therapy is needed to treat viral infections. It is fairly well distributed throughout the body, with CSF levels averaging two-thirds of those in plasma. Foscarnet is taken up slowly by cells, and biotransformation of foscarnet does not occur. The drug is excreted mainly unchanged in the urine (Chrisp and Clissold, 1991).

Foscarnet is used for the treatment of cytomegalovirus (CMV) retinitis and mucocutaneous acyclovir-resistant herpes simplex virus (HSV) infections. It may also be beneficial in other types of CMV or HSV infections (Wagstaff and Bryson, 1994).

In contrast to ganciclovir, foscarnet is not associated with dose-limiting neutropenia, enabling it to be used in combination with zidovudine and other bone marrow suppressant drugs. Nephrotoxicity and hypocalcemia are the major dose-limiting toxicities. Renal toxicity can be minimized with adequate hydration. Changes in serum calcium and phosphate levels may be related to incorporation of the drug into bone. Other adverse effects of the drug include tremor, headache, fatigue, nausea, and vomiting. Some cases of penile and vaginal ulceration have also been reported.

24.5.6. Cidofovir

Cidofovir (Figure 24.4) is an antiviral cytidine nucleotide analog with inhibitory activity against HCMV and other herpes viruses. Cidofovir is first converted to an active diphosphate form by cellular enzymes. Antiviral effects of cidofovir are due to inhibition of viral DNA polymerase by the diphosphate metabolite (Neyts and De Clercq, 1994; Plosker and Noble, 1999; Scholar and Pratt, 2000). The diphosphate probably interacts with DNA polymerase either as an alternate substrate (incorporation at the 3' end or within the interior of the DNA chain) or as a competitive inhibitor (with respect to the normal substrate dCTP). Cidofovir inhibits HCMV DNA synthesis at intracellular concentrations 1000-fold lower than are required to inhibit cellular DNA synthesis (Neyts and De Clercq, 1994). For HSV-1 and HSV-2 corresponding concentrations are at least 50-fold lower.

Cidofovir has poor oral bioavailability (<5%) and is therefore administered intravenously. It has a long intracellular half-life that allows for a prolonged interval between maintenance doses. Cidofovir is excreted extensively by the kidneys and

is eliminated almost entirely as unchanged drug in the urine (Plosker and Noble, 1999).

Standard treatment of CMV infections is with ganciclovir or foscarnet. The primary role in therapy of cidofovir is intravenous therapy in AIDS patients with cytomegalovirus retinitis who are unresponsive to or have relapsed on intravenous foscarnet or ganciclovir. It is also used in patients intolerant of these agents. Cidofovir may also be used to treat cytomegalovirus causing gastrointestinal tract infections. Its usefulness in neurological syndromes, pneumonitis, or viremia is unknown (Plosker and Noble, 1999).

Intravenous cidofovir is well tolerated. The major treatment-limiting toxicity of this drug is irreversible nephrotoxicity (Plosker and Noble, 1999). Intravenous pre-hydration with normal saline and administration of oral probenecid must be used with each cidofovir infusion to lessen the effects on the kidney. Serum creatinine and urine protein must be monitored with each infusion and adjusted accordingly. Other adverse effects associated with its use are neutropenia and peripheral neuropathy (Plosker and Noble, 1999).

24.6. West Nile Virus (WNV)-Induced Encephalitis

24.6.1. Summary of Virus Lifecycle and Virus Transmission

West Nile virus (WNV) (Figure 24.5) is a member of the Flaviviridae (Lindenback and Rice, 2001). WNV is a small positive-strand RNA virus that is approximately 11,000 bases long. Genomic RNA serves as a messenger RNA that is translated into a single polypeptide. This polypeptide is then cleaved into at least 10 discrete proteins by cellular proteases and a virally encoded serine protease. Three structural proteins (C, prM, and E) are produced from the polypeptide (Figure 24.5). Seven nonstructural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5) are generated from the polypeptide. NS5 is the most conserved protein in the Flaviviridae family because this protein is the viral-encoded RNA-dependent RNA polymerase. The other nonstructural proteins are not as well conserved, suggesting that they have virus-specific functions.

WNV has a broad range of antigenic variation and restriction-length polymorphisms, suggesting it is a highly variable virus. For example, strains from Africa, Europe, and the Middle East form a distinct group relative to strains isolated in India and the Far East (Price and O'Leary, 1967). WNV is widely disseminated throughout Africa, Europe, the Middle East, and the Far East. During the summer of 1999, WNV was introduced to the eastern coast of the U.S., and has subsequently moved westward.

WNV can be readily grown in a variety of mammalian cell lines, primary chick embryo fibroblast, primary duck fibroblasts, and *Drosophila* cells (Lindenback and Rice, 2001). In the wild, WNV is vectored by mosquitoes, and can infect

FIGURE 24.4. Cidofovir.

FIGURE 24.5. Schematic of West Nile Virus genome.

a variety of small rodents and birds. In addition, WNV can infect soft and hard ticks under natural and experimental conditions. Almost all species of birds tested (wild species, chickens, and pigeons) develop viremia. In the recent U.S. outbreak, the virus has killed a number of crows, and this has been used to track virus spread (Anderson et al., 1999). Sporadic cases of naturally acquired infections have been reported in horses, and these infections can lead to encephalitis. Bovine species do not develop viremia, but antibodies in cattle are prevalent. Finally, dogs are susceptible to infection, but low viremia levels preclude a significant role in virus transmission. Humans are a dead end host, but as described below, infections can be serious.

24.6.2. Pathogenesis of Encephalitis

The incubation period is 1–6 days, and the typical case is mild. Typical clinical features are fever, headache, backache, generalized myalgia, and anorexia. Rash occurs in about a half of the cases, and the rash is usually roseolar or maculopapular, and usually involves the chest, back, and upper extremities. The disease usually runs its course in 3–6 days, and is usually milder in children. Neurologic disease occurs in less than 1% of infected individuals. WNV can also cause severe, potentially fatal neurological disease, including encephalitis, meningitis, paralysis, and anterior myelitis. Although neurons are the primary target of WNV infection, a hallmark of WNV encephalitis is the accumulation of inflammatory infiltrates extending from the meninges in the brain parenchyma. These infiltrates are primarily comprised of lymphocytes and macrophages (Kelley et al., 2003). Most cases of WNV-induced encephalitis generally occur in older individuals, and treatment is supportive.

24.6.3. Animal Models for WNV

Mice have been used extensively to examine virus host interactions, and to examine virus-induced encephalitis. The adaptive immune response plays a crucial role in controlling WNV infections in mice, including encephalitis (Diamond et al., 2003; Shresta and Diamond, 2004; Wang et al., 2003). WNV infection leads to a Toll-like receptor 3-dependent inflammatory response, which promotes brain penetration of the virus, neuronal injury, and enhanced encephalitis (Wang et al., 2004). Since Toll-like receptor 3 recognizes double-stranded RNA and promotes an innate immune response, this finding

was somewhat surprising. The innate immune response also protects against WNV-induced encephalitis because when mice lacking the alpha/beta interferon receptor are infected with WNV an increase in the frequency of encephalitis is seen in mice (Samuel and Diamond, 2005). With the availability of a number of knockout mice, utilization of these mouse models to identify cellular factors that regulate WNV-induced encephalitis has a great deal of promise.

24.6.4. Therapy

Currently there is no established treatment for West Nile virus infections. Treatment consists only of supportive and symptomatic care, including support of respiration, intravenous fluids, and prevention of secondary infections.

24.7. Other Viruses that Can Induce Encephalitis

The viruses discussed below sporadically cause encephalitis. In many ways, these viruses can be considered as re-emerging viruses, and thus are important pathogens in certain parts of the world. A brief description of these viruses and how they induce encephalitis is therefore included in this review.

24.7.1. Flavivirus Family Members that Can Cause Encephalitis

24.7.1.1. St. Louis Encephalitis Virus

The St. Louis Encephalitis Virus (SLE) is a member of the Flavivirus family (Burke and Monath, 2001). SLE, like other Flaviviruses, contains a single stranded RNA genome that is approximately 11 kilobases in length. The SLE RNA is an mRNA that is translated into a large precursor protein. The large precursor protein is subsequently processed into the respective functional viral proteins. SLE is carried by a mosquito vector, *Culex* species, which is widely spread throughout the United States (Burke and Monath, 2001). The clinical syndromes associated with infection by SLE include: encephalitis, aseptic meningitis, and febrile headaches. In older patients (>60 years old), the severity of the disease is much worse, and this age group has the highest incidence of encephalitis. Only 2% of younger patients develop encephalitis whereas 22%

of patients who are 60 years or older develop encephalitis. In addition, the frequency of clinically apparent versus non-apparent infections is nearly 10 times higher in patients greater than 60 years old. The incubation period varies between 4–21 days after infection. The onset of disease has numerous non-specific symptoms; general malaise, fever, chills, headache, drowsiness, nausea, sore throat, and/or cough (Quick et al., 1965). Specific diagnosis relies on serologic tests because virus specific antibodies rise sharply after the first week of infection. Virus is not routinely present in CNS fluid making diagnosis difficult.

Between 1964 and 1968, there were 4,478 confirmed cases of SLE, which is considered as a major epidemic (Burke and Monath, 2001, Chamberlin, 1980). Major outbreaks of SLE seem to occur only once in approximately 10 years. During non-epidemic years, less than 50 cases occur in the United States. There is no specific treatment for SLE. Good supportive care is essential, in particular because of high fevers and convulsions caused by the virus.

24.7.1.2. *Japanese Encephalitis Virus*

The Japanese Encephalitis Virus (JEV) is a typical Flavivirus that is widely distributed in all parts of Asia (Burke and Monath, 2001, Podinger et al., 1996). About 50,000 cases are diagnosed each year in Asia, and of these cases 1000 deaths occur. Within Asia, there is a high degree of sequence variability for JEV suggesting certain sequence variants are more pathogenic than others. Children ranging from 3–15 have a tenfold higher incidence of clinical disease caused by JEV. Older individuals frequently have specific JEV antibodies suggesting they were infected, recovered, and then are protected from infection. Birds and swine are efficient hosts in which the virus can be amplified, and then spread to mosquitoes. Formalin-inactivated JEV is an effective vaccine that prevents encephalitis in humans. Travelers going to Asia are encouraged to get vaccinated.

A JE-like virus, Rocio virus, has been isolated from fatal human encephalitis cases during an outbreak of encephalitis in the 1970s on the south coast of Sao Paulo State, Brazil (Burke and Monath, 2001).

24.7.1.3. *Murray Valley Encephalitis Virus*

A JEV like virus, Murray Valley Encephalitis Virus (MVE), has been responsible for several sporadic epidemics of encephalitis in southern Australia (Burke and Monath, 2001, Doherty, 1977). Like SLE and JEV, MVE appears to be spread by mosquito vectors. Isolation of MEV from brain tissue or serologic tests is used for diagnosis. There is no specific treatment or vaccine that has been designed for MEV. As with JEV or SLE, treatment is supportive.

24.7.1.4. *Tick-Borne Encephalitis Viruses*

Tick-borne Encephalitis Viruses (TBE) has been recognized in nearly all countries within continental Europe (Burke and Monath, 2001). Seventeen antigenically related viruses com-

prise the TBE complex (Holzmann et al., 1993). Thirteen of these viruses can cause human disease, and all are vectored by ixodid ticks. Several vaccines have been developed against certain TBE members. Passive immunization is also effective in 60% of patients if the TBE-specific immunoglobulin is given within 4 days after a tick bite.

24.7.2. *Bunyaviridae and Their Role in Encephalitis*

24.7.2.1. *Summary of Bunyaviridae and Their Replication*

The Bunyaviridae encompasses a large group of viruses that have similar morphological, morphogenic, and antigenic properties (Schmaljohn and Hooper, 2001). For example, the Bunyaviridae contains four genera; Bunyavirus, Hantavirus, Nairovirus, and Phlebovirus. All members of these genera are arthropod-borne viruses. The Bunyaviridae virions contain three single-stranded RNA genome segments that are replicated and then translated (negative sense strand RNA). A virion associated polymerase replicates the viral RNAs, which subsequently serve as templates for translation.

24.7.2.2. *The Bunyavirus Genus and Its Role in Encephalitis*

The Bunyavirus genus contains at least 150 different viruses that can be found in all parts of the world except Australia (Nichol, 2001). Nearly all of these viruses are transmitted by mosquitoes and can be transmitted in several vertebrate hosts, including humans. The California encephalitis serogroup viruses cause more cases of human encephalitis than any other Bunyavirus member. Among the California encephalitis serogroup viruses, the LaCrosse virus is the most significant member with respect to causing encephalitis. The primary vector for La Crosse virus is a forest dwelling, tree hole-breeding mosquito (*A. triseriatus*). *A. triseriatus* are primarily found in the northern Midwest and northeastern United States, and thus more than 90% of the cases occur in these areas. Most La Crosse virus induced encephalitis occurs in summer and fall because this is the highest risk for being bitten by an infected female mosquito (Henderson and Coleman, 1971). The vector for Jamestown Canyon virus is *C. inonata* mosquitoes and several *Aedes* species, which are broadly distributed across North America. La Crosse virus primarily causes encephalitis in children, whereas the Jamestown Canyon virus causes encephalitis primarily in adults. The California Encephalitis serogroup of viruses is predicted to cause 60–130 cases of encephalitis each year.

In general, the California encephalitis subgroup viruses spread from the site of inoculation to skeletal muscles, which is the major site of replication. The virus then spreads to the lymphatic channels, thus spreading to additional skeletal muscles and cardiac muscles. Ultimately, the virus ends up in the CNS, where viral replication can occur in neurons and glial cells. Due to considerable neuronal necrosis, death can

occur 3 or 4 days after infection. Typical lesions in brains of fatal La Crosse encephalitis include cerebral edema, perivascular cuffing, glial nodules, mild leptomeningitis, and areas of focal necrosis (Kalfayan, 1983). There are no specific anti-viral drugs available for the California encephalitis serogroup viruses.

24.7.3. Rabies

The Rabies virus belongs to the Rhabdovirus family (*Lyssavirus* genus), and like all members of the Rhabdovirus family they are enveloped rod-shaped particles. The RNA genome is a non-segmented negative molecule that is approximately 11,000 nucleotides long (de Mattos et al., 2001). The RNA dependent RNA polymerase encoded by this family of viruses is essential for replicating the viral genome (Baltimore et al., 1970). Animal bites by rabid animals, in particular domestic dogs; cause more than 99% of all human rabies cases. The highest mortality rates are due to bites on the face or head because of the close proximity to the brain. Inhalation of aerosols, licks, or transdermal scratches from a rabid animal does not typically cause rabies because the virus cannot enter intact skin. The incubation period is usually 1–2 months, but there can be a great deal of variability for an incubation period. The length of incubation period depends on the bite site and relative proximity to the CNS, amount of virus delivered in the bite, age of the host, and immune status (Fishbein, 1991). Three general phases occur during the development of rabies: (1) the prodromal phase in which the symptoms are nonspecific (fever, chills, headache, nausea, diarrhea, muscle soreness, hydrophobia) that may last up to ten days, (2) acute neurologic phase in which patients exhibit nervous system symptoms (anxiety, agitation, hypersalivation, paralysis, and sporadic episodes of delirium, and (3) coma preceding death (de Mattos et al., 2001). Apart from hydrophobia, rabies induces similar clinical symptoms in animals.

Antibodies confer protective immunity, and thus it has been relatively easy to develop vaccines directed against rabies. The G protein of rabies is the only antigen that induces viral neutralizing antibody, protects against a lethal challenge, and consequently is the basis for a successful vaccine (Cox et al., 1977). Vaccination is crucial because there is no successful treatment directed against rabies. Supportive therapy can prolong life, but does not prevent death. Clinical diagnosis is relatively easy if exposure is documented. Many times, however, there is no history of exposure. Viral neutralizing antibodies, the presence of viral nucleic acids, or viral specific antigens can be readily obtained from patients prior to or following death (Hanlon et al., 1999). As expected, higher levels of viral products can be obtained from brain tissue of infected individuals during the latter stages of infection.

The domestic dog is the major vector for rabies throughout the world (de Mattos et al., 2001). Wild reservoirs for the virus can be found in foxes, raccoons, coyotes, jackals,

skunks, or bats. It will be difficult to eradicate the virus from wild animals because of the diverse population of animals that harbor the virus. Current veterinary vaccines are very effective, but like all vaccines they do not work 100% of the time. Domestic dogs are routinely vaccinated, and as such the incidence of rabid dogs has gone down. Wildlife can be effectively vaccinated by providing a potent oral vaccine that is contained within bait. As mentioned above, these vaccines are based on the Rabies virus G protein. Although rabies continues to be a threat to humans, it is not as serious as it was in the twentieth century. For example, from the 1980s to 1990s the annual number of rabies cases decreased from 350 to 114, and mortality rates fell from 1.3 to less than 0.2 per million people.

Summary

Viral induced encephalitis can result from infection by Herpes simplex virus, Varicella zoster virus, human cytomegalovirus, West Nile virus, Bunyavirae, Rabies, or specific family members of the Flavivirus family. Each of these viruses varies in properties; epidemiology, pathogenesis, clinical features and therapeutic approaches. This chapter discusses the clinical features, productive infection, latent infection, epidemiology, and pathogenesis, animal models used to examine encephalitis, and therapy of encephalitis for each of these viruses. The major drugs used to treat encephalitis caused by these viruses are acyclovir, valacyclovir, ganciclovir, cidofovir and foscarnet. For each of these drugs, we discuss the pharmacology, mechanism of action and adverse effects.

Review Questions/Problems

- 1. The treatment of choice for West Nile virus infection consists mainly of the use of**
 - a. acyclovir
 - b. steroids
 - c. ganciclovir
 - d. supportive and symptomatic care
 - e. tetracyclines
- 2. The most well known disease associated with cytomegalovirus infection is**
 - a. genital infections
 - b. retinitis
 - c. hepatitis
 - d. dementia
 - e. multiple sclerosis
- 3. Herpes simplex virus-2 infection occurs predominantly in**
 - a. the elderly
 - b. women

- c. homosexual men
- d. cancer patients
- e. sexually active adolescents

4. Which of the following best describes the mechanism of action of acyclovir?

- a. inhibition of reverse transcriptase.
- b. stimulation of viral interferon production
- c. inhibition of viral DNA polymerase
- d. inhibition of viral protein synthesis
- e. inhibition of de novo purine synthesis

5. Rabies virus contains

- a. a negative stranded RNA viral genome and humans contract it primarily from being bitten by a domestic dog.
- b. is only a problem in young children or older adults.
- c. can be effectively treated with anti-inflammatory agents.
- d. can only be grown in young mice.

6. Intravenous administration of acyclovir is most likely to cause

- a. anaphylactic shock
- b. renal toxicity
- c. liver toxicity
- d. bone marrow suppression
- e. cardiac arrhythmias

7. The main advantage of valacyclovir compared to acyclovir is

- a. a very short half life
- b. better oral bioavailability
- c. less renal toxicity
- d. it is useful for the treatment of HIV infection
- e. it has fewer drug interactions

8. Ganciclovir is best used for the treatment of

- a. West Nile virus
- b. herpes simplex encephalitis
- c. bird flu
- d. cytomegalovirus
- e. herpes zoster

9. Flavivirus family members that can cause encephalitis include

- a. herpes simplex virus type 1 and human cytomegalovirus.
- b. Rabies and St. Louis encephalitis virus
- c. West Nile virus
- d. Japanese encephalitis virus and St. Louis encephalitis virus

10. The major adverse effect associated with the use of cidofovir is

- a. bone marrow suppression
- b. rashes
- c. arrhythmias

- d. headaches
- e. nephrotoxicity

11. Foscarnet is

- a. a purine nucleoside analog
- b. a pyrimidine nucleoside analog
- c. incorporated into DNA resulting in inhibition of chain elongation
- d. an inorganic pyrophosphate analog
- e. a select inhibitor of RNA polymerase

12. Which of the following viruses causes encephalitis only in newborn children?

- a. West Nile virus
- b. herpes simplex virus type 1
- c. human cytomegalovirus
- d. varicella virus zoster
- e. all of the above

13. Why is HSV-1 induced encephalitis (HSE) difficult to treat with antiviral therapeutic drugs?

- a. Anti-viral drugs do not work because only drug resistant strains cause encephalitis.
- b. Many cases of encephalitis are the result of reactivation from latency.
- c. Early stages of infection are asymptomatic.
- d. Anti-viral drugs do not cross the blood brain barriers.
- e. all of the above

14. Effective vaccines have been developed against which virus

- a. herpes simplex virus type 1
- b. Japanese encephalitis virus
- c. rabies
- d. SV40

15. Circle all of the viruses that have the potential to induce encephalitis and establish a latent infection in neurons?

- a. HSV-1
- b. human cytomegalovirus
- c. West Nile virus
- d. varicella virus zoster
- e. SV40

16. The immediate early genes encoded by all herpesviruses regulate

- a. viral entry into permissive cells
- b. viral DNA replication
- c. production of antibodies by B cells
- d. viral gene expression
- e. all of the above

17. Is there a perfect correlation between the ability of viruses to replicate in the brain and induce encephalitis? Justify your answer.

- 18. If you were going to study viral induced encephalitis, would you choose HSV-1 or VZV as a model to identify viral genes that regulate the frequency of encephalitis? Give several reasons why you chose the virus that you chose.**

Fill in the blanks

- 19. _____ is a member of the Flaviviridae and has been spread by mosquitoes in North America.**
- 20. _____ is an alpha-herpesvirus family member that causes encephalitis and expresses LAT in latently infected neurons.**
- 21. _____ is an important opportunistic infection that causes retinitis in AIDS patients.**
- 22. _____ is an alpha-herpesvirus family member that causes chicken pox early in childhood and can cause zoster late in life.**
- 23. Describe the clinical features commonly associated with Herpes Simplex encephalitis.**

Alzheimer's Disease

Tsuneya Ikezu

Keywords Amyloid precursor protein; Apolipoprotein E; β -amyloid peptide; Beta-amyloid precursor protein converting enzyme; Insulin degrading enzyme; Neurofibrillary tangle; Oxidative damage; Presenilin-1

25.1. Introduction

Alzheimer's disease (AD) is the most frequent neurodegenerative disease and the most common cause of dementia in humans. Clinically, the classic and most frequent initial symptom is impaired short-term memory that progresses to profound memory failure. AD neuropathology exhibits two hallmark features: (1) senile plaques containing depositions of beta-amyloid protein and (2) neurofibrillary tangles (NFT). Quantitative neuropathological evaluation in early AD shows significant neuronal loss in brain memory regions. Genetic studies demonstrate that aberrant proteolytic processing of the amyloid precursor protein (APP) leads to 1–40 and 1–42 amyloid- β peptide (A β) fragments capable of causing AD pathology. However, the mechanisms by which amyloid proteins lead to plaque deposition, NFT, and neuronal cell death is incompletely understood. Thus, the objective of this chapter is to review what is known about disease mechanisms with a focus on the role played by neuroimmune interactions in neurodegenerative processes.

25.2. Clinical Features, Epidemiology, and Neuropathology

25.2.1. Symptoms (Memory Loss to Progressive Dementia)

AD is the leading cause of senile dementia and effective therapy remains in want (Sisodia, 1999). The symptoms of typical AD begin with a loss of short-term memory that slowly progresses to profound memory functions (Corey-Bloom et al., 1994). Initially, impaired short-term memory often manifests itself as

losing for forgetting the placement of objects or forgetfulness during conversations. Subsequently, other early cognitive deficits occur that include difficulty in finding words, problem solving and deficits in spatiotemporal awareness. Patients commonly appear depressed and apathetic. During the course of disease agitation and irritability often occur. With further disease progression, memory failure becomes more profound and longer-term memory is affected. Patients with these deficits are frequently disoriented and can easily become lost. Thus supervision of patients may become necessary. About this time, language skills and complex motor skills deteriorate. In still later stages, psychosis and hallucinations can occur along with bradykinesia and rigidity. Patients ultimately become bed-ridden, unable to speak, and succumb from infection or other medical conditions. The average survival time of Alzheimer's patients is 8 years after onset of initial symptoms but the rate of decline is variable.

25.2.2. Diagnosis

Of a large number of potential causes of dementia, AD is the most common. Hence to approach the diagnosis of AD evidence to support this diagnosis need be found to the exclusion of other possibilities. A definitive diagnosis includes: (1) a history obtained from someone who knows the patient well; (2) a physical and neuropsychiatric examination that excludes other neurologic and neurodegenerative disorders; (3) blood tests that exclude metabolic diseases involving the kidneys, liver, or thyroid; (4) a mental status test to determine dementia progression; and (5) brain imaging that exclude focal infection, inflammatory, and cancerous diseases (see Neuroimaging chapter for details). The first cognitive assessment widely used was the Mini-Mental State Examination (MMSE). MMSE assesses multiple cognitive tasks including spatiotemporal orientation, immediate/delayed word recall, naming, verbal repetition, reading, writing, and spatial ability (Folstein et al., 1975). There are multiple reports of reduced cognitive performance in pre-clinical AD, notably impaired function in abstract reasoning, episodic memory, and new learning (Fratiglioni et al., 2001).

Episodic memory deficits are dominant among early clinical and preclinical AD. A diagnosis of dementia is usually determined using the Diagnostic and Statistical Manual of Mental Disorders or DSM-IV of the American Psychiatric Association (Association, 1994). A final diagnosis is determined by the National Institute of Neurological Disorders and Stroke and Alzheimer's Disease and Related Disorders Association criteria, NINDS-ADRDA (McKhann et al., 1984). Other diagnosis standards includes the International Classification of Diseases (ICD)-10 guideline (Organization, 1992). Since DSM-IV and ICD-10 criteria closely follow NINDS-ADRDA guidelines, diagnostic procedures for AD are notably consistent worldwide. Given that AD is the primary cause of dementia, AD is often considered to be the likely cause of dementia while clinical tests are used to exclude other causes.

25.2.3. Epidemiology

AD affects more than four million people in the United States and prevalence studies demonstrate an exponential rise of dementia linked to advancing age (Katzman, 2001). The number of cases of dementia in the developed world is projected to rise from 13.5 million in 2000 to 21.2 million in 2025, and to 36.7 million in 2050 (Katzman and Fox, 1999). Currently the number of deaths caused by AD is similar to the number of deaths caused by stroke. AD and stroke together rank as the third most common causes of death (Ewbank, 1999).

In addition to age, other factors are associated with an increased risk of AD. In developed countries, AD appears to be more common in women. Lack of education is a risk factor for senile dementia in China and Europe (Zhang et al., 1990; Schmand et al., 1997). Head trauma is also a risk factor for both sporadic (Mortimer et al., 1991) and familial AD (Guo et al., 2000). Silent myocardial infarcts and coronary stenosis triple the risk for AD (Aronson et al., 1990; Sparks et al., 1990), suggesting the importance of vascular risk factors. Other potential risk factors being studied include diabetes and hypertension (Ott et al., 1999; Peila et al., 2002; Qiu et al., 2005). As discussed below, a large number of genetic mutations are now associated with either early-onset AD or with increased risk of late-onset AD.

Identification of genetic mutations that cause early onset AD has helped to dramatically increase the understanding of the origins of AD. Although cases of familial AD are relatively rare, they represent identified molecular mutations that cause AD. The genes identified to be responsible for early onset familial AD code for the amyloid precursor protein (APP), presenilin-1 and presenilin-2; these are found on chromosomes 21, 14, and 1, respectively. In addition to these dominantly transmitted disease-causing mutations in early onset AD, other studies have identified over 25 genetic risk factors that influence the appearance of the more common sporadic late onset AD. Current research is actively using genetically modified mice to determine how specific protein modifications lead to the pathology of AD.

25.2.4. Pathology

At autopsy, AD brains appear to have widespread neuronal and neuropil loss that thins cortical layers and expands ventricular and sulci spaces. However, there is not an obvious global loss of neurons in the cerebral cortex. Overall neuronal number appears relatively unchanged despite significant loss of brain tissue. Some of this apparent discrepancy is due to preferential loss of large pyramidal neurons in the cortex and relative sparing of smaller, densely packed neurons. Particularly vulnerable regions such as the entorhinal cortex and the CA1 of the hippocampus, show profound neuronal loss early in the disease. Wider involvement of temporal, frontal, and parietal cortices and a preferential loss of large neurons in these areas are seen as the disease progresses.

AD is characterized by an accumulation of senile plaques containing aggregated protein deposits of A β fibrils, numerous neurofibrillary tangles (NFTs), reactive astrocytes, and activated microglia in the neocortex and hippocampus (Alzheimer, 1907; Selkoe, 1997). Senile plaques can contain either a diffuse amyloid deposition (presumably early senile plaques) or a dense core of insoluble A β with neuritic structures (mature senile plaques). Although A β deposition and NFT are commonly observed in nondemented elderly 80 years and older, increased levels of senile plaques are seen in AD brains (Berg et al., 1993; Schmitt et al., 2000). The degree of both A β deposition and NFT formation are correlated with cognitive decline (Wilcock and Esiri, 1982; Berg et al., 1993; Braak and Braak, 1995; Naslund et al., 2000).

Although inflammation is a well-recognized phenomenon its precise definition is not yet established (McGeer and McGeer, 2001). Clinically, AD patients exhibit few of the classic signs of inflammation. Histopathologically, the classical acute inflammatory response (neutrophil recruitment), immunoglobulin precipitation, and T-cell accumulation are not seen suggesting that humoral or classical cellular immune-mediated responses are not involved in AD progression (Eikelenboom et al., 1994). However, AD brains show an increase in activated microglial clusters on senile plaques surrounded by astrocytes, indicating focal glial inflammation (Eikelenboom et al., 2002; Wyss-Coray and Mucke, 2002). In particular, volume density of CD68⁺ brain mononuclear phagocytes (MP; perivascular macrophages and microglia) is correlated with volume density of congophilic compact plaque deposits (Arends et al., 2000). CD68⁺ cells are present from very early preclinical phases to terminal phases of AD and are involved in disease progression, which will be further described later (Akiyama et al., 2000; Fonseca et al., 2004b). Moreover, deactivation of microglia has implications for therapy since long-term treatment of affected patients with nonsteroidal anti-inflammatory drugs (NSAIDs) has been shown to inactivate microglia and retard the development and progression of AD (in 't Veld et al., 2002), although NSAIDs may also directly affect the APP processing.

and accelerates A β aggregation and deposition in APP mice, which over-express Swedish FAD APP mutant in brains (Duff et al., 1996; Borchelt et al., 1997; Holcomb et al., 1998). PS2 FAD mutant over-expression converts A β 40 to A β 42, whereas PS2 wild type over-expression reduces both A β 40 and A β 42 (Mastrangelo et al., 2005). Taken together, these *in vivo* studies demonstrate the effect of PS1/2 FAD mutations on A β aggregation through transition of A β 40 to A β 42.

25.3.3. APP and PS1 Animal Models

Several established AD mouse models have made significant contributions to the understanding of AD pathogenesis (Price et al., 1998; Spires and Hyman, 2005). Analyses of AD brain tissue obtained from autopsies provide only limited insight into the dynamic nature of the disease process. Currently, no AD mouse model has all of the characteristics of the human disease. However, several lines of transgenic mice expressing mutated APP, such as PDAPP (Games et al., 1995), Tg2576 (Hsiao et al., 1996), APP23 (Sturchler-Pierrat et al., 1997), TgCRND8 (Chishti et al., 2001), APP^{swe} TgC3–3 (Borchelt et al., 1997), PSAPP (Holcomb et al., 1998), and 3xTg-AD mice (Oddo et al., 2003), simulate prominent behavioral and pathological features of AD. Phenotypes displayed by these mice include age-related impairments in learning and memory, electrophysiological abnormalities, neuronal loss, microgliosis, astrogliosis, neuritic changes, amyloid deposition, oxidative stress, and abnormal tau phosphorylation (Price et al., 1998; Smith et al., 1998) (Figure 25.2). Microglia in

FIGURE 25.2. 3D reconstruction image of amyloid plaque deposition and glial accumulation in APP mouse brain. Cortical section of Tg2576 (14 months of age) was stained by thioflavin-S (compact amyloid plaque, purple), anti-IBA1 rabbit polyclonal (microglia, red), and anti-GFAP mouse monoclonal (astrocytes, green), and imaged using a laser scanning confocal microscopy (Zeiss 510 Meta). Z-stack images were deconvolved and 3D reconstructed using image processing software (AutoQuant).

close proximity to fibrillar A β deposits are immunoreactive to interleukin (IL)-1 β and TNF- α , whereas activated astrocytes are immunoreactive to IL-1 β , transforming growth factor (TGF)-1 β , and IL-10 in Tg2576 mice (Frautschy et al., 1998; Benzing et al., 1999; Apelt and Schliebs, 2001).

Tg2576 mice which express Swedish familial AD mutant (K670N/M671L) of APP695 under a hamster prion promoter show memory and learning impairments as determined by Morris water maze (Hsiao et al., 1996). The memory recall is impaired as early as 6 months of age, which persists without significant progression for up to 12 months of age, followed by impairment of both memory acquisition and recall after 12 months of age (Lesne et al., 2006). There is a strong correlation of such age-related memory decline to A β accumulation in the brain (Figure 25.3) (Chen et al., 2000; Janus et al., 2000). A recent study in Tg2576 mice suggests that 9- or 12-mer A β oligomers are responsible for such memory loss, which can be isolated by Tg2576 and can induce transient memory loss in injected rodents (Lesne et al., 2006). Contextual fear conditioning tests, which represents hippocampal learning, show memory impairments in PDAPP mice as early as 4 months of age preceding the A β deposition (Jacobsen et al., 2006). These studies strongly suggest that onset of memory loss precedes the A β deposition, is more correlated with A β oligomer formation in the brain, may also be relevant to the clinical symptoms of AD patients.

25.3.4. β - and α -Processing Enzymes

Beta-site APP-cleaving enzyme (BACE1, also called Asp2 or Memapsin2), a β -secretase, is an aspartic transmembrane proteinase (Vassar et al., 1999). BACE2 (also called Asp1 and DRAP) is a homolog of BACE1 and contains the same overall structural organization. BACE1 is essential for A β production as demonstrated by BACE1 gene-targeted mouse models (Cai et al., 2001). BACE over-expression enhances total A β production, deposition of both diffuse and compact A β plaques in brain parenchyma, and reduces cerebrovascular amyloid angiopathy in aged APP/BACE double transgenic mice (Mohajeri et al., 2004; Willem et al., 2004). However, this effect seems to be dose-dependent, since high BACE expression rather inhibits A β deposition (Lee et al., 2005). Thus, the effect of BACE upregulation in A β pathology *in vivo* is not conclusive. A Disintegrin And Metalloprotease (ADAM) 9, 10, and 17 have been identified as putative α -secretases (Asai et al., 2003). Overexpression of ADAM10 prevents A β deposition and hippocampal defect in APP mice (Postina et al., 2004), suggesting its therapeutic application for enhancing α -processing of APP.

25.3.5. ApoE

ApoE is the most well characterized genetic risk factor of AD. Evidence indicates that endogenous apoE in mouse brain enhances A β deposition in APP animal models (Bales et al., 1999; Sadowski et al., 2004). Tg2576 mice lacking mouse apoE exhibit diminished compact plaque deposition, while diffuse

FIGURE 25.3. Schematic representation of the time course of A β deposition, A β oligomer accumulation, cognitive dysfunction, astrogliosis, and microgliosis in Tg2586 mice.

plaque load remained unchanged (Bales et al., 1999). Mouse apoE is rather amyloidogenic since apoE disruption significantly reduces the compact plaque formation in APP mice (Bales et al., 1999). In contrast, human apoE3 enhances A β clearance in mouse brain, while apoE4 weakly promotes A β clearance (Holtzman et al., 1999; Holtzman et al., 2000; Fagan et al., 2002). Although many studies concluded that astrocytes are the main apoE-producing cell in brain (Danik et al., 1999), recent reports suggest that microglial cells are also a source of apoE (Saura et al., 2003; Mori et al., 2004). A recent study of EGFP-ApoE knock-in mice demonstrated that apoE is expressed in 75% of astrocytes, and <10% of microglia after stimulation. Thus, apoE is primarily an astrocyte protein (Xu et al., 2006).

25.3.6. A β Degrading Enzymes

The current knowledge of A β degradation biology is limited since only a few of the molecules involved have been characterized, namely insulin degrading enzyme (IDE) and neprilysin, which is also known as enkephalinase, and neutral endopeptidase metalloendopeptidase (NEP) (Yamin et al., 1999; Iwata et al., 2000; Selkoe et al., 2001). IDE was originally identified as a microglia-secreted A β degrading enzyme (Qiu et al., 1998), and is also found in neurons (Vekrellis et al., 2000). Neprilysin protein level is downregulated during aging, but is locally upregulated in activated astrocytes surrounding A β plaques in APP mice (Apelt et al., 2003). Thus the amount of IDE and neprilysin can be altered by chronic inflammatory reaction. Neprilysin, a neutral zinc metallopeptidase, plays a role in degrading insoluble and/or aggregated A β 42 (Iwata et al., 2000; Selkoe et al., 2001). Transgenic expression of both IDE and neprilysin show inhibition of A β accumulation in APP mice (Leissring et al., 2003). In addition, endothelin converting enzyme and matrix metalloprote-

ase-2 and 3 are also new candidates of A β degrading enzymes (Choi et al., 2006; White et al., 2006).

25.3.7. Neurofibrillary Tangle Formation

Presence of NFT is one of the original neuropathological hallmarks of AD. NFT are fibrous tangles composed of insoluble, conformationally abnormal, hyperphosphorylated tau protein deposited in neuronal cell bodies. Hyperphosphorylated tau can form a specific insoluble structure known as a paired helical filament (PHF) (Buee et al., 2000; Lee et al., 2001). Six tau protein isoforms are generated by alternative mRNA splicing of the *tau* gene. Based on the repeat of the intermediate microtubule binding domain, the majority of tau is classified as three repeat (3R) or four repeat (4R) tau. The primary function of tau is to bind to and stabilize microtubules, thereby promoting microtubule polymerization. Many tau phosphorylation sites flank microtubule binding domains and are believed to play a significant role in its microtubule binding (Lee et al., 2001; Planel et al., 2002). Hyperphosphorylation of tau appears to cause tau to dissociate from microtubules and form tau protein aggregates, which becomes PHF (Biernat et al., 1993; Bramblett et al., 1993; Alonso et al., 1996). Glycogen synthase kinase 3- β (GSK3 β), cyclin dependent protein kinase 5/p25 complex, microtubule affinity regulating kinase, and recently tau-tubulin kinase 1 have been extensively characterized as tau kinases that seem to be involved in the hyperphosphorylation of tau (Ishiguro et al., 1992; Takashima et al., 1993; Drewes et al., 1997; Patrick et al., 1999; Sato et al., 2006).

Tau-related neurodegenerative disorders, or “tauopathies,” include AD, argyrophilic grain dementia, corticobasal degeneration, diffuse neurofibrillary tangles with calcification, Down’s syndrome, frontotemporal dementia and Parkinsonism linked to chromosome 17 (FTDP-17), Gerstmann-Straussler-Scheinker

disease, Niemann-Pick disease, non-Guamanian motor neuron disease with neurofibrillary tangles, Pick's disease, progressive supranuclear palsy, subacute sclerosing panencephalitis, and tangle only dementia (Lee et al., 2001). Genetic studies show that missense mutations in the *tau* gene (*Mtapt*) induce FTDP-17 supporting its importance in tauopathies (Hutton et al., 1998; Lee et al., 2001), although such mutations have not been found in AD. These tau mutations develop similar pathology in transgenic animal models, such as P301L tau mouse (Lewis et al., 2000; Gotz et al., 2001a), R406W tau mouse (Sato et al., 2002), G272V tau mouse (Gotz et al., 2001b), and V337M tau mouse (Tanemura et al., 2002). However, P301L tau mice develop NFT-like tau aggregation not only in CNS but also in peripheral motor neurons, astrocytes and oligodendrocytes, that is correlated with gait disturbances (Lewis et al., 2000).

25.3.8. Neurotoxicity and Synaptic Dysfunction

25.3.8.1. $A\beta$ -Mediated Neurotoxicity

It has been widely accepted that toxicity of $A\beta$ requires aggregation of native $A\beta$ monomers (Hardy and Higgins, 1992; Pike et al., 1993). $A\beta$ ($A\beta$ 40 or $A\beta$ 42) self-assembles to form low-n oligomers (dimers-hexamers), protofibrils, and fibrils (Roher et al., 1996; Harper et al., 1997; Walsh et al., 1997; Lambert et al., 1998). Since intermediates can further associate into higher-ordered aggregates, it is difficult to determine the oligomerization state of $A\beta$ that causes pathogenicity. Nonetheless, several groups succeeded in isolating spherical non-fibrillar assemblies of synthetic $A\beta$ ($A\beta$ -derived diffusible ligands; ADDLs and amylospheroid; ASPD) (Lambert et al., 1998; Hoshi et al., 2003). These $A\beta$ oligomers show more potent toxicity than fibrillar $A\beta$ at lower concentrations (Lambert et al., 1998) and induce reversible synaptic loss through N-methyl-D-aspartate (NMDA) receptor interaction in organotypic hippocampal culture systems (Shankar et al., 2007). Thus, $A\beta$ oligomers are a likely therapeutic target (De Felice et al., 2004).

$A\beta$ can also potentially mediate neurotoxicity by activating microglia and glia and hereby promoting their secretion of a variety of neurotoxic factors. $A\beta$ and secreted β -amyloid precursor protein (sAPP)-induce microglial activation and neurotoxicity (Giulian and Baker, 1986; Meda et al., 1995; Barger and Harmon, 1997; Ikezu et al., 2003). Neurotoxicity can be mediated through secretion of neurotoxic agents such as FasL, tumor necrosis factor (TNF)- α , reactive oxygen species (ROS), proteases, excitatory amino acids, and nitric oxides. Excitatory amino acids (glutamate, quinolinic acid, D-serine, among others) activate N-methyl-D-aspartate (NMDA) receptors, which are significantly involved in microglial-mediated neurotoxicity (Piani et al., 1992; Giulian et al., 1994). Indeed, both $A\beta$ and sAPP activated microglia increase glutamate secretion (Barger and Basile, 2001; Ikezu et al., 2003). Glutamate and ROS can exacerbate each other's neurotoxic effects due to their relationships with the cystine/glutamate exchange system (Xc⁻)

antiporter. $A\beta$ /sAPP-induced microglial activation leads to ROS production and glutathione consumption, that in turn promotes cystine import to regenerate glutathione and, as a consequence, increased glutamate is exported in exchange through the Xc antiporter (Ikezu et al., 2003).

25.3.8.2. $A\beta$ -Mediated Synaptic Dysfunction

There are a number of studies documenting the synaptic dysfunction of APP mice, which starts as early as 4 months of age, including enhanced paired-pulse facilitation, disturbed high frequency stimulation (HFS) burst, and rapid decay of LTP in the CA1 field of hippocampal slices (Hsia et al., 1999; Larson et al., 1999). In addition, impaired synaptic transmission and LTP in both the CA1 and DG regions are also evident in Tg2576 mice (Chapman et al., 1999). $A\beta$ oligomers block hippocampal long-term potentiation (LTP) *ex vivo* at nanomolar concentrations. *In vivo* applications of $A\beta$ oligomers potently inhibit rat hippocampal LTP and cognitive function (Walsh et al., 2002; Cleary et al., 2005). These studies strongly suggest that $A\beta$ oligomers induce memory impairment through inhibition of synaptic transmission and long-term potentiation in brain. One of the potential mechanisms of $A\beta$ -induced LTP inhibition is through the activation of a number of inflammation-related molecules, such as c-jun N-terminal kinase, CDK5, p38 mitogen-activated kinase, inducible nitric oxide synthase, and superoxide, (Wang et al., 2004a; Wang et al., 2004b). These data suggest significant involvement of microglial activation in the inhibitory mechanism.

25.3.8.3. Neurotoxicity by Tau Aggregation

Although NFT is a hallmark of AD, its direct involvement in neuronal cell death is still unclear. Presence of NFT does not appear to be highly toxic since clinical studies suggest long-term survival of NFT-bearing neurons (Morsch et al., 1999; Hof et al., 2003). These data are also supported by studies using FTDP-17 tau mutant mice showing NFT formation in the absence of neuronal cell loss (Santacruz et al., 2005) and a lack of cognitive impairment as assessed by a water maze test (Arendash et al., 2004). A new doxycycline-inducible tau transgenic mouse model suggests accumulation of intracellular tau protein rather than NFT formation is responsible for neurodegeneration and cognitive impairment (Ramsden et al., 2005; Santacruz et al., 2005). However, tau is known to be involved in $A\beta$ aggregate-induced neurotoxicity in conjunction with protein kinase activation *in vitro* (Rapoport et al., 2002; Hoshi et al., 2003; Medina et al., 2005). Thus, it is possible that acute neuronal cytoskeletal destabilization by tau phosphorylation and its end-product (globular tau aggregates) are neurotoxic, but its subsequent subcellular compartmentalization as NFT/PHF is a preventive neuroprotective process used to contain neurotoxic aggregates. Further study will be necessary to characterize its effect on neurodegeneration or dementia.

25.4. Immunity and AD

Neuronal loss, edema, and recruited mononuclear phagocytes (moving from blood to brain), are all classical hallmarks of brain inflammation in AD (Arvin et al., 1996). Gliosis, characterized by activation, proliferation, and hypertrophy of astrocytes and microglia, is one important feature of neuroinflammation. Amyloid plaques contain a number of proteins including complement proteins and pro-inflammatory cytokines and chemokines. Many of these proteins are secreted by activated microglia and reactive astrocytes. Activated microglia integrate deeply into neuritic plaques and express major histocompatibility complex type II (MHC-II), a marker for microglial activation. MHC-II expression is significantly upregulated in AD brains (Rogers et al., 1988; Styren et al., 1990).

Neurotoxicity can be mediated through secretion of various factors, ROS, proteases, excitatory amino acids, and nitric oxides. Pro-inflammatory cytokines and chemokines can inhibit fibrillar A β phagocytosis by a murine microglial cell line (Koenigsknecht-Talboo and Landreth, 2005). Such T-cell-mediated cytokines also inhibit post-phagocytosis intracellular A β degradation in human monocyte-derived macrophages. A β -microglia interaction results in two outputs: phagocytosis and signaling for priming and activation. A β binding to a complex of cell surface proteins (including CD36, integrin-associated protein (CD47), and $\alpha_6\beta_1$ -integrin) leads to src-like tyrosine kinase activation and ROS production (Bamberger et al., 2003). CD36 is necessary for full A β -induced mononuclear phagocyte activation and chemotaxis (El Khoury et al., 2003). These findings strongly suggest that A β aggregates activates microglia by its binding to specific cell surface molecules, which activates src-like tyrosine kinases and other signaling for A β clearance and neuroinflammation in AD brains.

25.4.1. Microglia-Mediated A β Clearance

Our current knowledge of A β clearance is limited compared to the more detailed understanding of A β synthesis and aggregation mechanisms. It is well known that A β stimulation enhances microglial phagocytosis, *in vitro* (Kopec and Carroll, 1998). The internalized A β in phagosomes initially migrate to acid hydrolase-containing late endosomes and lysosomal compartments, and then moves into perinuclear vesicles, that are morphologically similar to lysosomes, where it stays up to 20 days (Paresce et al., 1997). The long-term accumulation of A β has also been observed by using unlabeled A β aggregates in bone marrow-derived macrophages (Yamamoto et al., 2007a). In addition to microglia, astrocytes also contribute to the uptake and removal of A β in a manner enhanced by a CC-type chemokine, CCL2 (Wyss-Coray et al., 2003).

Microglia constantly take-up A β via potential A β receptors, including scavenger receptor type A (SR-A), CD36, and receptor for advanced glycation end product (RAGE) (El Khoury et al., 1996; Yan et al., 1996; El Khoury et al., 2003). Although SR-A was characterized as a major receptor for microglial

phagocytosis of A β (Paresce et al., 1996), APP mice deficient in SR-A show no difference in amyloid plaque formation or synaptic degeneration (Huang et al., 1999). This suggests that other scavenger receptors or A β -binding molecules, such as CD36, CD47, and $\alpha_6\beta_1$ -integrin, can compensate for the deficiency of SR-A. On the other hand, RAGE seems to enhance A β deposition. APP mice deficient in RAGE exhibit reduced A β deposition (unpublished observations), which is consistent with enhanced A β deposition in mice over-expressing RAGE (Arancio et al., 2004). P-glycoprotein (Pgp), an ATP binding cassette transporter/multidrug resistance-1 α and β gene, is another molecule involved in A β clearance from brain parenchyma. Disruption of Pgp exhibits enhanced A β deposition, suggesting its role in endothelial efflux of A β from the brain (Cirrito et al., 2005).

25.4.2. Glial Inflammation and Innate Immunity

Innate immune responses in AD are mediated by a large number of inflammatory proteins, such as complement factors, acute-phase proteins, pro-inflammatory cytokines, and chemokines (Akiyama et al., 2000; McGeer and McGeer, 2001). Upregulation of the complement system includes activation of both classical and alternative pathways and enhanced secretion of cytokines and chemokines including, but not limited to, IFN- γ , IL-1 α/β , IL-6, IL-8, IL-12, TGF- β 1/2, TNF- α , CD40L, CCL2 (MCP-1), CCL3 (MIP-1 α), CCL4 (MIP-1 β), S100- β (for review, see (Akiyama et al., 2000)). The interplay between A β aggregates, microglia and astrocytes results in secretion of proinflammatory cytokines that, in turn, may affect local APP expression in nearby neurons. This process results in local upregulation of A β and seeding of "new" A β deposits, which may therefore be a potential mechanism for the plaque accumulation typically seen in AD brains.

25.4.2.1. Cytokines

25.4.2.1.1. IL-1

IL-1 upregulation seems to occur early in A β plaque formation since it is associated with diffuse plaques and also found in young children with Down's syndrome (Griffin et al., 1989; Griffin et al., 1995). IL-1 induces S100 β , an astrocyte-derived neurite promoting cytokine (Kligman and Marshak, 1985), and α 1-antichymotrypsin (Das and Potter, 1995). IL-1 upregulates APP synthesis in primary astrocytes (Rogers et al., 1999), and A β production when co-stimulated with IFN- γ *in vitro* (Blasko et al., 2000).

25.4.2.1.2. IFN- γ

IFN- γ is produced by Th1 type T cells and natural killer cells (Young and Hardy, 1995), as well as macrophages (Fultz et al., 1993), astrocytes, and microglia (DeSimone et al., 1998). IFN- γ affects A β production, A β degradation (Yamamoto et al., 2007b), and neurotoxicity (Meda et al., 1999). IFN- γ , in conjunction with TNF- α , has been shown to enhance APP

mRNA transcription and A β production (Blasko et al., 1999), and indirectly induce neuronal loss by stimulating release of NO from microglia (Chao et al., 1995). In the Tg2576 mouse model, astrocytes significantly upregulate IFN- γ mRNA *in vivo* (Abbas et al., 2002). We have recently found that transgenic APP mice (Tg2576) lacking IFN- γ receptor type I show marked reduction of A β deposition, microgliosis, astrogliosis, and astrocytic BACE expression (Yamamoto et al., 2007b). Thus, IFN- γ plays an important role for AD pathogenesis.

25.4.2.1.3. IL-6

IL-6 is a pleiotropic proinflammatory cytokine, secreted from T cells, macrophages, astro/microglia, and is involved in a number of inflammatory signals, including the acute phase response. IL-6 and its receptor complex, IL-6R and gp130/CD130, are all upregulated in AD brains in a region-specific manner (Hampel et al., 2005). IL-6 immunoreactivity is colocalized with diffuse plaques but not with compact plaques (Hull et al., 1996), suggesting its role in diffuse plaque reaction rather than compact plaque formation. Astrocyte-derived IL-6 induces expression of complement component C3, and may be involved in complement cascade activation in AD (Barnum et al., 1996).

25.4.2.1.4. TGF- β 1/2/3

TGF- β 1/2/3 are expressed in the CNS and are involved in development, homeostasis, and repair (Finch et al., 1993). TGF- β 1 has been detected in plaques (van der Wal et al., 1993) and is elevated in cerebrospinal fluid and serum in AD (Chao et al., 1994b; Chao et al., 1994a). TGF- β 2 has also been detected in reactive astrocytes, microglia, and in tangle-bearing neurons in AD brains (Wyss-Coray et al., 2000). TGF- β 1 transgenic mice show cerebrovascular amyloid deposition (Wyss-Coray et al., 1997). Over-expression of TGF- β 1 in APP mice accelerates vascular amyloid deposition although plaque burden was reduced in brain tissue (Wyss-Coray et al., 1997; Wyss-Coray et al., 2001), suggesting its role in clearing A β from brain parenchyma. Since TGF- β 1 increases APP expression in astrocytes and microglia (Gray and Patel, 1993; Monning et al., 1994; Harris-White et al., 1998), it may also be involved in TGF- β 1 glial A β production. Disruption of TGF- β 1 induces neurodegeneration and microgliosis (Brionne et al., 2003). APP mice over-expressing kinase-deficient TGF- β receptor type II, which inhibits endogenous TGF- β signaling, show enhanced A β deposition, neurodegeneration, and dendritic loss (Tesseur et al., 2006).

25.4.2.1.5. TNF- α

TNF- α , a pleiotropic proinflammatory cytokine, has been extensively investigated in AD. TNF- α is predominantly expressed by activated microglia, and to a lesser extent, astrocytes and neurons (Meda et al., 1995; Botchkina et al., 1997; Bezzi et al., 2001; Williams et al., 2005). In AD, TNF- α is upregulated in cerebrospinal fluid (Tarkowski et al., 1999), serum (Fillit et al.,

1991), and cortex (Tarkowski et al., 1999). The effect of TNF- α on neurons is different dependent on the neuronal preparation and perhaps species; it is neurotrophic to rat cortical, hippocampal, and septal neurons (Cheng et al., 1994; Barger and Harmon, 1997), while directly neurotoxic (or enhances glutamate neurotoxicity) to human cortical neurons (Chao and Hu, 1994; D'Souza et al., 1995; Williams et al., 2005). This discrepancy could be due to the diverse signaling of two distinctly different TNF- α receptors, type I (p55 TNFR-1) and type II (p75 TNFR-2) (Botchkina et al., 1997; Dziewulska and Mosakowski, 2003). TNFR-1, but not TNFR-2, contains an intracellular death domain, common to proteins in the TNF receptor family. TNFR-1 mediates both apoptosis and NF- κ B-mediated cell survival (Wallach et al., 1999; Gupta and Gollapudi, 2005). Importantly, primary cultured hippocampal neurons derived from TNFR-1 null mice were resistant to A β -mediated neurotoxicity (Li et al., 2004). Thus, TNF- α -mediated neurotoxicity is bidirectional and the outcomes of TNF signaling depend distinctly on cell type and species.

25.4.2.1.6. CD40L

CD40L belongs to the TNF family and one of the most important T-cell mediated cytokines. CD40, the receptor of CD40L, is upregulated by A β -stimulation of primary cultured microglia *in vitro* (Tan et al., 1999) and is found to be expressed in reactive microglia in AD patient brain tissue (Togo et al., 2000). Transgenic APP (Tg2576) mice deficient in CD40L show reduced A β deposition, astro/microgliosis, and hyperphosphorylation of tau (Tan et al., 2002). In addition, chronic treatment of APP/PS1 biogenic mice with neutralizing anti-CD40L antibody reduces A β deposition and causes a modest improvement in cognitive performance (Tan et al., 2002; Todd Roach et al., 2004), suggesting its therapeutic application for AD.

25.4.2.2. Chemokines

25.4.2.2.1. CCL2 (MCP-1)

CCL2 (MCP-1) is a member of the β chemokine subfamily and a candidate molecule for stimulating monocyte chemotaxis into the CNS (Charo et al., 1994). Activated astrocytes and cells of monocytic origin (such as microglia and macrophages) have been shown to express CCL2 in the brain (Calvo et al., 1996; Glabinski et al., 1996). CCL2 has been detected in senile plaques, reactive microglia and microvessels in AD brains (Ishizuka et al., 1997; Xia and Hyman, 1999; Grammas and O'vase, 2001), and is upregulated in cerebrospinal fluid and serum of AD cases and AD animal models (Sun et al., 2003; Galimberti et al., 2005; Janelins et al., 2005). Over-expression of CCL2 resulted in increased diffuse plaque deposition, microglial accumulation, and apoE expression in APP mice (Yamamoto et al., 2005), accompanied by cognitive impairment (Yamamoto, M et al., unpublished observations). These results show that CCL2/CCR2 signaling is critical in mononuclear phagocyte accumulation and A β deposition in CNS.

25.4.2.2.2. CXCR Family

A number of other chemokines and their receptors have been identified in AD. CXCR2 is a member of the CXC chemokines receptor family and is a receptor for multiple ligands, including CXCL1/2/3 (GRO α / β / δ) (Zlotnik and Yoshie, 2000). Both CXCR2 and CXCL1 have been detected in AD brains. In particular, CXCR2 expression has been identified in dystrophic neurites of senile plaques (Xia et al., 1997). CXCR3, another CXC receptor family, and its ligand CXCL10 (IP-10) have been found in both cortical and subcortical neurons in normal and AD brains. CXCL10 was significantly upregulated in AD brain (Xia et al., 2000). In addition, expression of CC chemokine receptors, such as CCR3 and CCR5, and their ligands, CCL4 (MIP-1 β) and CCL5 (RANTES), is also enhanced on reactive microglia in AD brain (Xia et al., 1998). Although the exact physiological functions of these molecules have yet to be characterized in the context of AD pathogenesis, modulation of such chemokine signaling might be beneficial to correct the detrimental imbalance of metabolic homeostasis and neuroinflammation in brain.

25.4.2.3. Toll-Like Receptors

One of the most important recent findings in the effort to understand innate immunity has been the identification of Toll-like receptors (TLRs). TLRs define a major class of pattern-recognition receptors critical to the initiation and tailoring of both innate and subsequent adaptive immune responses (Beutler, 2004; Iwasaki and Medzhitov, 2004). For example, bacterial cell wall components are recognized by TLR2, and lipopolysaccharide and viral envelope proteins are recognized by TLR4. Double strand RNA, single strand RNA, and unmethylated CpGs are recognized by TLR3, TLR7/8, and TLR9, respectively (for review, see (Akira et al., 2006)). Primary cultured human and mouse microglia express mRNA for TLR1–9, whereas human and mouse astrocytes express high levels of TLR3, and low-level TLR 1, 2, and 4–6 (Olson and Miller, 2004; Jack et al., 2005) (Carpentier et al., 2005; McKimmie and Fazakerley, 2005). A recent study on aged mouse brains demonstrated that TLR1, TLR2, TLR4, TLR5, TLR7 and CD14 expression were upregulated in correlation with age, whereas TLR9 was downregulated (Letiembre et al., 2007). Interestingly, a TLR4 polymorphism was also associated with successful aging (Candore et al., 2006), which further indicates a role of innate immune receptors in aging and potentially AD.

The role of TLRs in neuroinflammation during AD is poorly characterized. However, recent reports indicate that TLR9 ligand (CpG-containing oligonucleotide) induced enhancement of A β uptake by N9 microglia cell line (Iribarren et al., 2005), and A β stimulation modulates TLR-specific inflammation (NO and TNF- α release) in primary cultured mouse microglia (Lotz et al., 2005). These results suggest that there is crosstalk between A β and TLR signaling that may regulate glial inflammation and A β clearance in CNS.

25.4.2.4. Matrix Metalloprotease

A β stimulation induces robust expression of matrix metalloprotease (MMP) 1, 3, 10, 10, 12, 19, and disintegrin and metalloprotease (ADAM) 8 in primary cultured human microglia (Walker et al., 2006). Increased expression of MMP 1, 3 and 9 has been documented in AD brains (Backstrom et al., 1996; Leake et al., 2000; Yoshiyama et al., 2000) and may contribute to tissue damage (Cuzner and Opdenakker, 1999). These molecules may be involved in A β degradation, cytokine/chemokine processing, and shedding of cell adhesion molecules for enhancing glial motility.

25.4.2.5. Other Inflammatory Molecules: Complement Complex and CD45

Complement C1q, the first complement of the classical complement pathway, is upregulated in AD brains and is found in senile plaques (Afagh et al., 1996). C1q binds to soluble A β and modulates its uptake by mononuclear phagocytes (Webster et al., 2000). C1q also directly induces neurotoxicity through its interaction with cell surface calreticulin, a C1q receptor (Luo et al., 2003). However, APP mice lacking C1q exhibited reduced glial and astroglial activation without changes in A β deposition (Fonseca et al., 2004a). Thus, C1q may be involved in AD pathogenesis by influencing neurotoxicity and glial inflammation, but its effect on A β metabolism is modest.

Complement C3 is upregulated in APP/TGF- β 1 biogenic mice and AD brains (Wyss-Coray et al., 2001). Over-expression of soluble complement receptor-related protein y (sCrpy), a complement C3 inhibitor, resulted in enhanced A β accumulation and hippocampal degeneration (Wyss-Coray et al., 2002). Since C3 is known to promote phagocytosis by binding to specific C3 receptor on specialized cells, C3 is likely to be positively involved in A β clearance.

CD45, a transmembrane protein tyrosine phosphatase critically involved in negative regulation of T- and B-cell activation, and an antagonizing partner of the TNF superfamily (Tan et al., 2000a), is also upregulated in AD brains (Masliah et al., 1991). APP mice deficient in CD45 have increased brain levels of TNF- α and NO, suggesting CD45 negative regulation of neuroinflammation in AD (Tan et al., 2000b).

25.4.3. Oxygen Free Radicals

Production of ROS, factors involved in the aging process (Finkel and Holbrook, 2000), is elevated in AD brain and may be an important cause of AD (Martins et al., 1986). Elevated levels of oxidized lipids (lipid peroxidation, malondialdehyde, 4-hydroxynonenal) (Markesbery and Carney, 1999), proteins (advanced glycation end product modifications, tyrosine nitration) (Good et al., 1996; Takeda et al., 1998), and nucleic acids (8-hydroxy-deoxyguanosine) have been documented in AD brains (Lyras et al., 1997). Mitochondria and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex

dysfunction can generate large amounts of ROS (Beal, 1998), and down regulation of mitochondrial NADPH 15-kD gene have been found in AD cases (Beal, 1998; Manczak et al., 2004). Markers of oxidative stress are elevated not only in the pathologic lesions in AD brain (Good et al., 1996), but also in cerebrospinal fluid of AD patients (Lovell et al., 1997). A β peptide can directly activate the NADPH oxidase complex of mononuclear phagocytes (Bianca et al., 1999) and microglia, which are mediated through the interaction of fibrillar A β to cell surface molecules (CD36, CD47, and α 6 β 1-integrin) and tyrosine kinase Vav signaling (Wilkinson et al., 2006). ROS is also known to mediate A β -induced neurotoxicity (Behl et al., 1994; Ikezu et al., 2003). In addition to NADPH oxidase, myeloperoxidase (MPO) is expressed by microglia in close proximity to A β plaques, and surprisingly, in neurons of AD brains (Reynolds et al., 1999; Green et al., 2004). MPO can catalyze both apoE and A β , generating oxidated and fragmented apoE (Jolivald et al., 1996) and stable A β 42 dimers through dityrosine bridge formation (Jolivald et al., 1996; Galeazzi et al., 1999).

25.4.3.1. Oxidative DNA Damage

DNA damage may also have a role in AD pathology. Recent studies indicate that aging-mediated DNA damage, including alterations in neuronal network and cognitive function-related gene expression profiles, is significantly increased after 40 years of age, (Lu et al., 2004). DNA damage induces cell cycle activation (Kruman et al., 2004), and cell cycle activation has been documented in AD brains (Nagy et al., 1998; Smith et al., 1999). DNA damage also potentially induces p53, a tumor suppressor and transcriptional factor involved in neuronal apoptosis (Morrison et al., 2003; Kruman et al., 2004; Culmsee and Mattson, 2005). Neuronal expression of p53 is increased in AD brains (de la Monte et al., 1997) and in APP mouse brains (LaFerla et al., 1996). These data suggest that DNA damage is involved in neurodegeneration in AD brain, or the result of neurodegeneration.

25.5. Immunopharmacology

Epidemiological studies using nonsteroidal anti-inflammatory drugs (NSAIDs) has led to the proposal that NSAIDs reduce the risk of AD (McGeer et al., 1996). These studies have been supported by data showing that treatment of APP mice with NSAIDs (such as ibuprofen and NO-flurbiprofen) *in vivo* results in reduced A β deposition and pro-inflammatory cytokine production (Lim et al., 2000; Jantzen et al., 2002; Yan et al., 2003). Microglial activation is suppressed by ibuprofen but rather enhanced by NO-flurbiprofen. Other studies have found that NSAID also affects γ -processing of APP through inhibition of the small GTP-binding protein Rho, which shifts A β processing from A β 42 to A β 40 both *in vitro* and *in vivo* (Weggen et al., 2001; Eriksen et al., 2003; Zhou et al., 2003). Based on these observations, a new series of drugs derived

from NSAIDs having a more specific effect on γ -processing has been developed (Kukar et al., 2005).

Proliferator-activated receptor γ (PPAR γ) agonists, such as the thiazolidinedione family, are also NSAIDs and can efficiently clear A β deposition *in vitro* and *in vivo* (Camacho et al., 2004; Heneka et al., 2005). PPAR is a nuclear transcription factor and its effect is different from ibuprofen and its derivatives. PPAR γ transcription factors play important physiological roles in the regulation of lipid metabolism (Mangelsdorf et al., 1995; Lemberger et al., 1996), suppression of inflammation (Heneka et al., 2000), and clinical treatment of diabetes type II (Dormandy et al., 2005). PPAR γ agonists enhance A β degradation (Camacho et al., 2004), as well as suppress BACE expression and microglial activation (Heneka et al., 2005).

Other anti-inflammatory/antioxidant dietary applications include curcumin, the yellow pigment in turmeric that targets multiple AD pathogenic cascades (Lim et al., 2001; Yang et al., 2005). The dietary omega-3 fatty acid, docosahexaenoic acid (DHA), also reduced amyloid, oxidative damage and synaptic and cognitive deficits in a transgenic mouse model (Calon et al., 2004; Lim et al., 2005). Both DHA and curcumin have favorable safety profiles, epidemiology and efficacy, and may exert general anti-aging benefits (Cole et al., 2005).

Summary

AD is the most common form of elderly dementia and has no effective therapy. Clinical diagnosis is based on the evaluation of cognitive function and lab tests. Pathological diagnosis is based on post-mortem neuropathology, defined by three hallmarks: senile plaque, NFT, and neuronal cell loss. Senile plaque mainly consists of A β aggregates and serves as a focal point of astrocyte and microglial activation, while NFT contains hyperphosphorylated tau. A β is produced during the processing of APP by BACE and the γ -secretase complex that includes PS1. Both APP and PS1 are causative genes of AD, while apoE4 is a risk factor allele. The A β load in CNS is maintained by balancing its production and clearance, which is mediated by passive diffusion to blood stream, degradation by A β degrading enzymes (IDE and neprilysin), and microglial phagocytosis. A β production, deposition, and neurodegeneration are significantly regulated by astroglial and microglial activation via direct contact as well as secretion of a number of neurotoxins. Specific pro-inflammatory cytokines, chemokines, and excitotoxins have been characterized as mediators of neuroinflammation and neurotoxicity. Currently their specific roles in mediating the pathogenesis in AD are being explored. Those diverse studies are generating a large number of potential therapeutic targets for treating AD. Beneficial effects have been reported for anti-inflammatory drugs, such as NSAIDs, to treat glial inflammation and disease progression.

Review Questions/Problems

- Which is NOT the causative gene of familial Alzheimer's disease?**
 - APP
 - Presenilin-1
 - Presenilin-2
 - Tau
 - None of the above
- Presenilin-1 is a member of:**
 - α -secretase
 - β -secretase
 - γ -secretase complex
 - A β degrading enzyme
 - None of the above
- Amyloid-beta peptide is a processing product of amyloid precursor protein (APP) through a combination of**
 - α -secretase and Beta-site APP cleaving enzyme (BACE1)
 - α -secretase and γ -secretase complex
 - BACE1 and γ -secretase complex
 - BACE1 and insulin-degrading enzyme
 - none of the above
- Microglia-mediated inflammatory reaction affects AD progression via**
 - cytokine production
 - reactive nitrogen/oxygen production
 - excitotoxin production
 - all of the above
 - none of the above
- A β deposition in APP mouse brain can be reduced by vaccination with the following antigens except**
 - A β
 - apoE4
 - Copaxon-1
 - transgenic potato expressing amyloid-beta peptide
 - none of the above
- Nonsteroidal anti-inflammatory drugs (NSAIDs) can reduce A β deposition in APP mouse brain through**
 - suppression of brain inflammation
 - suppression of A β 42 generation
 - suppression of BACE expression
 - all of the above
 - none of the above

Parkinson's Disease

Serge Przedborski

Keywords Dopamine; Glial-derived neurotrophic factor; Lewy body; Leucine-rich repeat kinase 2; MPTP; Nigrostriatal pathway; Paraquat; Parkin; Rotenone; Alpha-Synuclein

26.1. Introduction

In this chapter the topic of inflammation in Parkinson's disease (PD) and in models of human disease will be reviewed. To set the stage, the biological, clinical and pathological hallmarks of PD and related degenerative conditions will be presented. A more comprehensive review of PD can be found in the following two references (Fahn and Przedborski, 2005; Dauer and Przedborski, 2003).

PD is the second most frequent neurodegenerative disorder of the aging brain after the dementing disorder, Alzheimer's disease (AD). It is estimated that more than one million individuals in the United States are affected with PD and around 50,000 new cases are identified each year. The main clinical features of PD include resting tremor, slowness of movement, rigidity, and postural instability. As many other prevalent neurodegenerative disorders discussed in this book including AD and amyotrophic lateral sclerosis (ALS), PD presents itself essentially as a sporadic condition, i.e. in absence of any genetic linkage. However, as in AD and ALS, only a small fraction of PD patients inherit the disease. In some of these familial cases the genetic defect has been identified and linked to mutations in a variety of genes (Vila and Przedborski, 2004). The clinical manifestations seen in both the sporadic and the familial forms of PD have all been attributed to a profound deficit in brain dopamine (Hornykiewicz and Kish, 1987). Given this fact, it is not surprising that most attention has been geared toward the study of dopaminergic pathways in PD.

Autopsy investigations have revealed that most ascending dopaminergic pathways are affected in PD, though to different degrees (Hornykiewicz and Kish, 1987); the

nigrostriatal is consistently more affected than any other (Hornykiewicz and Kish, 1987). The nigrostriatal pathway is made up of dopaminergic neurons whose cell bodies are located in the substantia nigra pars compacta and their projecting axons and terminals in the striatum (Figure 26.1A). Among these dopaminergic neurons, it appears that those with the highest content of brown pigment called neuromelanin are the ones most prone to degeneration (Hirsch et al., 1988). Contrasting with the damage to the ascending pathways, the descending dopaminergic pathways are generally spared (Hornykiewicz and Kish, 1987). If the most salient clinical symptoms of PD are indeed related to the damage of the dopaminergic system in the brain, it cannot be stressed enough that degenerative changes in PD are neither restricted to the nigrostriatal pathway nor other dopaminergic systems (Hornykiewicz and Kish, 1987; Agid et al., 1987). For instance, abnormal histological features can also be found in many non-dopaminergic cell groups including the locus coeruleus, raphe nuclei, and nucleus basalis of Meynert (Braak et al., 1995).

Aside from the loss of neurons, all affected areas of the brain in PD also contain intraneuronal proteinaceous inclusions called Lewy bodies (Galvin et al., 1999). These inclusions can be readily visualized by either classical histological methods, e.g. hematoxylin & eosin, or by immunohistochemistry using antibodies raised against alpha-synuclein or ubiquitin (Figure 26.1B, C). Often, Lewy bodies are large, round, and occupy most of the cytoplasmic area of the few spared neurons. While identification of these proteinaceous inclusions is usually used for neuropathological diagnostic purposes, the actual pathogenic role of Lewy bodies remains controversial. Another, but often overlooked, salient neuropathological feature of PD is the presence of inflammatory change within affected regions (Forno et al., 1992; McGeer et al., 1988). This inflammatory response is the topic of this chapter and will be described in further details below.

FIGURE 26.1. Neuropathology of Parkinson's disease. (A) Schematic representation of the normal nigrostriatal pathway (in red). It is composed of dopaminergic neurons whose cell bodies are located in the substantia nigra pars compacta (SNpc; see arrows). These neurons project (thick solid red lines) to the basal ganglia and synapse in the striatum (i.e. putamen and caudate nucleus). The photograph demonstrates the normal pigmentation of the SNpc, produced by neuromelanin within the dopaminergic neurons. (B) Schematic representation of the diseased nigrostriatal pathway (in red). In Parkinson's disease, the nigrostriatal pathway degenerates. There is marked loss of dopaminergic neurons that project to the putamen (dashed line) and a much more modest loss of those that project to the caudate (thin red solid line). The photograph demonstrates depigmentation (i.e. loss of dark-brown pigment neuromelanin; arrows) of the SNpc due to the marked loss of dopaminergic neurons. (C) immunohistochemical labeling of intra-neuronal inclusions, termed Lewy bodies, in a SNpc dopaminergic neuron. Immunostaining with an antibody against α -synuclein reveals a Lewy body (black arrow) with an intensely immunoreactive central zone surrounded by a faintly immunoreactive peripheral zone (left photograph). Conversely, immunostaining with an antibody against ubiquitin yields more diffuse immunoreactivity within the Lewy body (right photograph). 26.2. Inflammatory Response in Parkinson's Disease

Before discussing the issue of inflammation in PD *per se*, it is worth reviewing briefly the question of innate resident immune cell topography in the normal brain. In a healthy

adult brain, microglia constitutes roughly 10% of all glial cells and are not evenly distributed (Lawson et al., 1990). In an unstimulated situation, microglia exhibit elongated, bipolar shaped cell bodies with spine-like processes that often branch perpendicularly. Among the areas of the brain susceptible to the PD process, the density of microglia identified by the labeling of the specific plasma membrane glycoprotein F4/80 is higher in the substantia nigra compared to other regions of the brain, at least in adult mice (Lawson et al., 1990). In contrast to microglia, astrocytes in the normal adult brain are homogeneously distributed, except in the midbrain where the estimated density of glial fibrillary acidic protein (GFAP)-positive cells varies among the different catecholaminergic groups (Damier et al., 1993). The density of GFAP-positive cells is moderate in the midbrain areas most severely affected in PD, such as in the substantia nigra pars compacta, and high in those least affected, such as the central gray matter (Damier et al., 1993). Furthermore, it has been reported that the density of GFAP-positive cells within the substantia nigra pars compacta is lowest in the calbindin-D_{28K}-poor pockets (Hirsch et al., 1999), which have been previously identified as the zones of the substantia nigra pars compacta where the loss of dopaminergic neurons is the highest (Damier et al., 1999).

Because of the notoriety of the nigrostriatal dopaminergic damage in PD, information regarding inflammation in this common neurodegenerative disorder pertains essentially to the substantia nigra and the striatum. Consistently, it has been found that the loss of dopaminergic neurons in post-mortem PD brains is associated with microgliosis and astrogliosis (McGeer et al., 1988; Forno et al., 1992; Banati et al., 1998; Mirza et al., 2000). However, these changes have always been found to be more intense in the substantia nigra pars compacta than in the striatum (McGeer et al., 1988). This situation contrasts with that of the loss of dopaminergic structures, which is more intense in the striatum than in the substantia nigra.

At the cellular level, the majority of the immunostained astrocytes in PD exhibit a resting-like morphology, with thin, like-shaped cell bodies and elongated processes, while only few exhibit a reactive morphology with hypertrophic cell bodies and short processes (Mirza et al., 2000; Forno et al., 1992). Furthermore, there seems to be only a minimal increase in astrocyte numbers when GFAP- or metallothionein I/II-positive cells are quantified (Mirza et al., 2000). Unlike the astrocyte alterations discussed above, the microglial changes in PD are striking (McGeer et al., 1988; Banati et al., 1998; Mirza et al., 2000; Imamura et al., 2003). Morphologically, microglial cells in both the substantia nigra and striata of PD patients, unlike of controls, typically exhibit thick, elongated processes (McGeer et al., 1988; Banati et al., 1998; Mirza et al., 2000). The number of these activated microglia, identified by HLA-DR or ferritin immunostaining, is much higher in PD than in controls (Mirza et al., 2000;

Imamura et al., 2003). Activated microglia are mainly found near free neuromelanin in the neuropil and remaining neurons in the substantia nigra (McGeer et al., 1988). Similar microglial activation is also found in the striatum (Imamura et al., 2003).

26.3. Inflammatory Response in Parkinsonian Syndromes

While PD is the most common of the parkinsonian syndromes, more than 30 different neurological syndromes share the clinical features of PD (Dauer and Przedborski, 2003). Many of these non-PD parkinsonian syndromes are sporadic (Table 26.1) and often exhibit both clinical (e.g. ocular movement) and neuropathological features not typically seen in PD (e.g. striatal or corticospinal track pathology). Of these syndromes most, if not all show at autopsy evidence of nigrostriatal neurodegeneration (not always associated with Lewy bodies) and inflammation (Oppenheimer and Esiri, 1997). Unfortunately, inflammation is casually mentioned in most published reports on non-PD parkinsonian syndromes, and when the authors of these reports do mention inflammation it is often limited to vague, qualitative statements. For instance, in the initial reports of progressive supranuclear palsy (Steel et al., 1964) and striatonigral degeneration (Adams and Salam-Adams, 1986), *gliosis* was recognized as a prominent feature of the pathological changes seen in these syndromes, but is the sole reference to inflammation. However, whether or not gliosis, as mentioned in these studies, refers to alterations in astrocytes, microglia, or to both, remains unknown. Despite this limitation, it is remarkable that gliosis is not only described in these non-PD parkinsonian syndromes at the level of the nigrostriatal pathway, but also at the level of other regions in the brain, which are normally not involved in PD. This indicates a rather widespread neuropathology which is consistent with the usual multisystemic nature of many of these parkinsonian syndromes (Table 26.1).

Aside from sporadic parkinsonian syndromes, several familial forms also exist (Vila and Przedborski, 2004). Like in sporadic PD, histological examinations revealed similar glial alterations in most of the familial forms of parkinsonian syndromes, whether the underlying genetic defect has (Vila and Przedborski, 2004) or has not been identified (Dwork et al., 1993). Among these familial parkinsonian syndromes, the situation of the autosomal dominant form of PD linked to mutations in the gene coding for leucine-rich repeat kinase 2 (LRRK2) is interesting (Zimprich et al., 2004). In the six autopsies from patients carrying a LRRK2 mutation reported by Zimprich and collaborators (2004), all had nigrostriatal dopaminergic neuronal loss and gliosis in the substantia nigra. However, some of these patients had dopaminergic neuronal loss and gliosis without Lewy bodies, whereas others had dopaminergic neuronal loss and gliosis with Lewy bodies (Zimprich et al., 2004). In the latter cases, Lewy bodies were

TABLE 26.1. Parkinsonian syndromes.

Primary parkinsonism
Parkinson disease (sporadic, familial)
Secondary parkinsonism
Drug-induced: dopamine antagonists and depletors
Hemiatrophy-hemiparkinsonism
Hydrocephalus: Normal pressure hydrocephalus
Hypoxia
Infectious: Post-encephalitic
Metabolic: Parathyroid dysfunction
Toxin: Mn, CO, MPTP, cyanide
Trauma
Tumor
Vascular: Multiinfarct state
Parkinson-plus syndromes
Cortical-basal ganglionic degeneration
Dementia syndromes: Alzheimer disease, diffuse Lewy body disease, frontotemporal dementia
Lytic-Bodig (Guamanian Parkinsonism-dementia-ALS)
Multiple system atrophy syndromes: Striatonigral degeneration, Shy-Drager syndrome, sporadic olivopontocerebellar degeneration (OPCA), motor neuron disease-parkinsonism
Progressive pallidal atrophy
Progressive supranuclear palsy
Familial neurodegenerative diseases
Hallervorden-Spatz disease
Huntington disease
Lubag (X-linked dystonia-parkinsonism)
Mitochondrial cytopathies with striatal necrosis
Neuroacanthocytosis
Wilson disease

Notes: MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; ALS; amyotrophic lateral sclerosis. (From Dauer and Przedborski, *Neuron* 39:889-909, 2003, with permission.)

restricted to the brainstem, or widespread in the brainstem and cortex. In one case, there were also *tau*-immunoreactive lesions not only in neurons, but also in glial cells (Zimprich et al., 2004). In the autosomal recessive parkinsonian syndrome linked to *parkin* mutations there is also a loss of dopaminergic neurons associated with gliosis but, as in several LRRK2 mutation cases, not typically with Lewy bodies (Hayashi et al., 2000). These findings support the view that inflammation is a generic phenomenon that arises from neuronal death irrespective of the type of parkinsonian syndrome or neuropathological picture. It also suggests that the presence of Lewy bodies is not a prerequisite for the occurrence of inflammation in PD and related conditions.

26.4. Inflammatory Response in Experimental Models

As discussed above, studies performed in autopsy tissues from patients afflicted with parkinsonian syndromes have led to the conclusion that inflammation is part of the neuropathological picture of these neurodegenerative disorders. While the descriptive data provided by these studies are invaluable, the

generated information remains correlative by nature and fails to provide mechanistic insights. This is why researchers rely heavily on experimental models of PD. These models help to define the temporal and topographical relationships between inflammation and dopaminergic neuronal death and, more importantly, to determine the potential pathogenic role of inflammation in the death of dopaminergic neurons.

Experimental models of PD are multiple and can be genetic or toxic (Dauer and Przedborski, 2003). The neuropathological picture created in these models, particularly in the toxic models, is very close to that described in PD. In almost all of the PD models, whether or not there is an overt loss of nigrostriatal dopaminergic neurons, a glial response is found in the substantia nigra. Some data on inflammation are available from rodent models produced by the herbicide paraquat (McCormack et al., 2002) and the mitochondrial poison rotenone (Scherer et al., 2003). Some data can also be found from transgenic mice expressing mutant alpha-synuclein (Gomez-Isla et al., 2003). The limited amount of data on inflammation in these models however is in striking contrast with the wealth of information available for the 6-hydroxydopamine (6-OHDA) and the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) toxic models of PD. Perhaps this can be explained by the fact that both the 6-OHDA and MPTP models are not only more popular among PD researchers, but also they have been used for much longer than the other models cited above. Supporting the generic nature of the inflammatory response in neurodegeneration are the observations that both the type and magnitude of the glial alterations in rodents following the administration of 6-OHDA (Nomura et al., 2000; Przedborski et al., 1995; Sheng et al., 1993; Stromberg et al., 1986; Rodrigues et al., 2001; He et al., 1999; Akiyama and McGeer, 1989) are comparable to those seen following the administration of MPTP (see below).

In the early eighties, several drug addicts got intoxicated with MPTP after self-injecting contaminated street-batches of meperidine analog (Langston et al., 1983). Among these individuals, some developed an acute, irreversible parkinsonian syndrome indistinguishable from PD (Ballard et al., 1985). Of the few MPTP-intoxicated individuals who died and underwent an autopsy, post-mortem examination showed a profound loss of nigrostriatal dopaminergic neurons (Davis et al., 1979; Langston et al., 1999). This dramatic loss of large neuronal cells was associated with the obvious abundance of small cells, immunoreactive for either the astrocyte marker GFAP or the microglia marker HLA-DR (Langston et al., 1999). Almost all GFAP- and HLA-DR-positive cells exhibited morphological characteristics of respectively reactive astrocytes and activated microglia (Langston et al., 1999). Images of neuronophagia were also observed (Langston et al., 1999). Similar glial alterations were found in six monkeys, which survived 5–14 years after an acute MPTP intoxication (McGeer et al., 2003). In all of these monkeys, there was also evidence of extracellular neuromelanin and activated microglia in the substantia nigra (McGeer et al., 2003). These

monkeys also had an abundance of reactive astrocytes positive for the intracellular adhesion molecule-1 (Miklossy et al., 2005). The presence of intracellular adhesion molecule-1-positive reactive astrocytes, of activated microglia, and of neuronophagia in humans and monkeys subjected to an acute MPTP intoxication many years prior is remarkable as these neuropathological features suggest an active, ongoing inflammatory process. Microglial activation and neuronophagia would be expected to be seen in PD tissues in light of its progressive neurodegenerative nature. However, as stressed by McGeer and collaborators (2003), these neuropathological findings challenge the belief that MPTP, 'produces an acute loss of cells, followed by healing and long-term stabilization of surviving neurons'. Alternatively, these neuropathological data raise the possibility that an acute MPTP intoxication can set in motion a self-sustained cascade of detrimental effects on dopaminergic neurons. Corroborating this view is a positron emission tomography study in which ten individuals exposed acutely to MPTP were scanned twice, seven years apart (Vingerhoets et al., 1994). This work revealed a decrease of [^{18}F]fluorodopa uptake in the striata of these patients between the first and second imaging studies (Vingerhoets et al., 1994). Also remarkable is the fact that three of the ten MPTP-intoxicated participants were asymptomatic at the time of the first scan but became parkinsonian by the time of the second scan (Vingerhoets et al., 1994) supporting a progression of the neurodegenerative process in this toxic parkinsonian syndrome, at least in primates.

In small animals such as mice, time course experiments have been performed to define not only the kinetics of dopaminergic neuronal death but also of the glial response. These studies demonstrated that the appearance of reactive astrocytes paralleled the destruction of dopaminergic structures in both the striatum and the substantia nigra in mice (Czlonkowska et al., 1996; Kohutnicka et al., 1998; Liberatore et al., 1999). Worth noting, GFAP expression remained high even after the main phase of neuronal degeneration (Czlonkowska et al., 1996; Kohutnicka et al., 1998; Liberatore et al., 1999). Also important to note is the fact that upon inhibition of the entry of the active metabolite MPTP, 1-methyl-4-phenylperydinium (MPP^+), into dopaminergic neurons there is not only a protection of substantia nigra dopaminergic neurons, but also a lack of glial response (O'Callaghan et al., 1990). This critical observation indicates that inflammation in the MPTP model is a consequence of the demise of neurons and not the reverse. This interpretation may not be valid for all types of injury used to model PD as we will see for the endotoxin of gram-negative bacteria lipopolysaccharide (LPS). The activation of microglial cells is also quite robust after MPTP administration in mice (Figure 26.2); this has been extensively documented in the MPTP mouse model (Czlonkowska et al., 1996; Kohutnicka et al., 1998; Liberatore et al., 1999; Dehmer et al., 2000). When the astrocytes and microglia responses are compared, however, it appears the microglial activation occurs earlier than that of astrocytes, and peaks just before or coincidentally

FIGURE 26.2. Effects of MPTP on dopaminergic neurons and glial cells in ventral midbrain of mice. For this illustration, mice received either 0.3 ml of MPTP (2 mg/ml) or vehicle (saline) in one day. (A,E) Two days after the last injection of MPTP, TH immunofluorescence (blue) reveals a marked reduction in dopaminergic neurons in the substantia nigra pars compacta compared to controls (saline). (B,C,F,G) The loss of TH labeling coincides with an increase in immunofluorescent labeling of microglial cells (Mac-1; green) and of astrocytes (GFAP; red). (D,H) Overlay of the three cellular markers. When MPTP and saline tissue sections are compared, these images show that upon reduction in the dopaminergic neuronal marker, there is an increase in the two glial markers. Ventral midbrain tissue sections (30 μ m) were immunostained with a rabbit polyclonal anti-TH (1:1000; Calbiochem, San Diego, CA), a rat anti-MAC-1 (1:1000; Serotec, Raleigh, NC), and a chicken anti-GFAP (1:500, Chemicon, Temecula, CA). Scale bar = 200 μ m.

to, the climax of dopaminergic neurodegeneration (Liberatore et al., 1999).

In addition to the response of the innate immune system in the MPTP mouse model, there has also been some descriptive data from Czełonkowska and collaborators (Kurkowska-Jastrzebska et al., 1999a, b) about the response of the adaptive immune system. Although this question will be developed in-depth in the chapter authored by Dr. Lee Mosley, herein it is included as a brief informative aspect. In the series of investigations performed by Czełonkowska and collaborators cited above, a marked increase of MHC-II antigen expression by microglia, accompanied by a recruitment of T-cells in both the ventral midbrain and striatum of MPTP-injected mice, were found. Contrasting with the infiltration of the diseased areas of the brain with T-cells, there was no B-cell in the tissue samples. The investigators went further into their characterization of the adaptive immune system in this model by showing that the infiltrating T-cells were mainly of the CD8+ type, but some CD4+ were present too, and more than 50% of the observed lymphocytes expressed the CD44 antigen.

26.5. Initiation of the Inflammatory Response in Parkinsonian Brains

If indices of inflammation are well recognized in tissues from virtually all neurodegenerative disorders including PD, how

inflammation begins, remains enigmatic. In reviewing the literature, two main hypotheses are emerging. One hypothesis posits that inflammation precedes and triggers the actual loss of dopaminergic neurons. Based on this model, the starting point of the neurodegenerative process would be an insult to the brain by pro-inflammatory factors such as LPS or other infectious-related molecules. Relevant to this possibility is the demonstration that a stereotaxic injection of LPS into a normal substantia nigra pars compacta produces a local inflammatory response associated with a degeneration of dopaminergic neurons in adult rats (Liu et al., 2000). Similarly, LPS-induced inflammation led to the neurodegeneration of dopaminergic MES 23.5 cells or primary ventral midbrain neurons co-cultured with purified microglia (Le et al., 2001). Based on a series of investigations in rodents it seems that even a prenatal exposure to LPS could produce a long-lasting inflammatory response in the brain (Ling et al., 2004). This striking observation led the authors to propose that ‘individuals exposed to LPS prenatally, as might occur had their mother had bacterial vaginosis, would be at increased risk for PD’.

As much as the first hypothesis appears tantalizing the most available data are rather consistent with this second hypothesis which posits that inflammation in PD results from the detection of pathological alterations in neighboring neurons by the immune system. According to this model, inflammation in PD and related disorders is thus not a primary event, but instead the consequence of neurodegeneration. However,

how dysfunctional or dying neurons elicit the inflammatory response remains unknown. Many glial cells are located in close proximity to neurons. Therefore, it may very well be that inflammation could be initiated by some type of change in the nature or the quality of the neuronal contact with glial cells. In healthy cells including neurons, phosphatidylserine is located at the cytoplasmic side of the plasma membrane, while the outer monolayer is composed of phosphatidylcholine and sphingomyelin. A loss of this phospholipid asymmetry of the plasma membrane, with appearance of phosphatidylserine in the outer membrane leaflet, is a feature of cells undergoing apoptosis (van den Eijnde et al., 1998). It is thus possible that such an alteration of the neuronal membrane could be detected by the neighboring glial cells, leading to their activation.

Cell culture studies also show that inflammation can be triggered by soluble factors, either secreted or leaked by neurons. For instance, chromogranin-A is a glycoprotein widely distributed in the nervous system, which was shown to accumulate in areas of neurodegeneration (Nishimura et al., 1994). Noteworthy is the fact that once released or leaked by neurons, chromogranin-A could activate microglia (Ciesielski-Treska et al., 1998). Furthermore, dopaminergic neurons in both PD and experimental models of PD are the site of a robust induction of cyclooxygenase-2 (Teismann et al., 2003), which is a key prostaglandin-synthesizing enzyme. It is also plausible that once synthesized, prostaglandins exit neurons and activate their cognate receptors expressed by glial cells, whereby triggering inflammatory events. Similarly, neuromelanin upon its release in the extracellular space from dying neurons can strongly activate glial cells (Wilms et al., 2003). Finally, it has also been suggested that misfolded neuronal proteins and protein aggregates may contribute to glial activation in PD. This view has been prompted by the observations that mutations in the genes encoding for parkin and ubiquitin C-terminal hydrolase L1—two enzymes of the ubiquitin/proteasome pathway—and for alpha-synuclein—a main component of the intraneuronal proteinaceous inclusions Lewy bodies—are linked to familial PD (Vila and Przedborski, 2004).

Although more work needs to be done to identify the factors that initiate inflammation in PD and related disorders, mounting evidence indicates that this immune response is probably not a standard event of dysfunctional and dying neurons. Currently, most researchers favor the idea that *specific* neuronal-derived molecules bind to *specific* transmembrane receptors, such as toll-like receptors (TLRs) present on glial cells (Bowman et al., 2003). Among the ten different TLRs, each is activated by a distinct ligand (Iwasaki and Medzhitov, 2004). Although activation of TLRs has been studied thus far in the context of infection, it is now believed that inflammation in neurodegenerative disorders arises from the ligation of the particular TLR subtypes by molecules originating from dysfunctional and dying neurons. Relevant to this idea is the demonstration of wild-type alpha-synuclein, which upon overexpression can cause a familial form of PD (Eriksen et al., 2005), and is secreted by neurons through unconventional exocytosis (Lee et al., 2005). Furthermore, it appears that the

expression of markers of microglial activation parallels the extent of alpha-synuclein deposits in the substantia nigra of PD patients (Croisier et al., 2005). At this point, it would be quite interesting to know whether alpha-synuclein or any other mutant proteins linked to familial PD can bind to TLRs.

26.6. Role of Inflammation in Parkinson's Disease

Over the past decade, the idea that brain inflammation (sometimes called neuroinflammation) may modulate the neurodegenerative process in disorders like PD has attracted a major interest among neuroscientists. How can this be explained given the fact that inflammation is likely a consequence of neurodegeneration? Neurons in all degenerative diseases die in an asynchronous manner (Pittman et al., 1999). Accordingly, in PD, dopaminergic neurons in the substantia nigra pars compacta do not die simultaneously. Instead, only a small number of dopaminergic neurons are dying at any given time and, among these, many are at various stages along the cell death process. Based on these premises, it may thus be envisioned that the very first neurons to succumb trigger inflammation. Thereafter, the cellular environment in which compromised, living neurons are embedded becomes inflamed. Should this scenario be correct, it is trivial to understand how inflammation could modulate the neurodegenerative process.

While most experts do agree on the idea that glial cells play a role in the neurodegenerative process, the significance and, more importantly, the direction, of the effect remains a matter of fierce debate (Streit, 2002). The dispute is fueled in part by the fact that both *in vitro* and *in vivo* system models of human diseases have revealed both detrimental and beneficial effects of inflammation. For instance, the blockade of the microglial activation by minocycline has been associated with either reduction or augmentation of dopaminergic neurodegeneration after MPTP administration (Du et al., 2001; Wu et al., 2002; Yang et al., 2003; Diguett et al., 2004). These divergent results may stem from the fact that inflammation is capable of exerting both neuroprotective and neurodestructive functions. Thus, depending on local factors, the extent of the degenerative process, and even the etiology of the disease, inflammation can give rise to quite a distinct molecular and cellular phenotype.

26.7. Beneficial Role of Inflammation in Parkinson's Disease

Several *in vivo* studies support the capacity of inflammation in mediating neuroprotective and neurodegenerative properties in the nervous system. One such example is the facial nerve axotomy paradigm in newborn rats and rabbits. In this system model, axotomized motor neurons recover coincidentally with the development of the glial response (Moran and Graeber, 2004). It was also shown that a month after implantation of

innate immune resident cells such as microglia into a small mechanically produced cavity in the rat spinal cord, prominent neuritic growth was observed in the microglial grafts (Rabchevsky and Streit, 1997). These results are agreed upon by some experts who believe that under both normal and pathological situations, the function and survival of neurons rely on the presence of glial cells (Streit, 2002).

The basis of glial-derived beneficial role is likely multifactorial involving both cell contact and soluble mediators. For instance, glial cells play a critical role in maintaining ion and pH homeostasis, and extracellular volume. Glial cells can also protect neurons by scavenging and taking-up toxic molecules released by dysfunctional and dying neurons. A striking example of glial assistance in the process of neuronal well-being is glutathione, which is a tripeptide of great importance in the protection of neurons against reactive oxygen species (ROS). Indeed, unlike glial cells, neurons do not possess an uptake system for cysteine (Pow, 2001) which is necessary for the synthesis of glutathione. Instead it has been proposed (Dringen, 2000) that astrocytes assist neurons in their production of glutathione through a complex multistep process. First, the astrocytes would use extracellular substrates as precursors for glutathione. Second, glutathione would be released by astrocytes and then converted by the glial ectoenzyme gamma-glutamyl transpeptidase into the dipeptide CysGly. Third, CysGly would be taken-up by neurons and used as a precursor to neuronal glutathione. It has also been proposed (Dringen, 2000) that glutamine produced by astrocytes would be used by neurons to produce glutamate, which is necessary for the synthesis of glutathione. Finally, astrocytes, can avidly take up extracellular glutamate via the glutamate transporters GLT1 and GLAST. This fact may be quite relevant to PD pathogenesis as not only an excess amount of glutamate in the substantia nigra may emanate from dying neurons but also from the subthalamic glutamatergic input (Benazzouz et al., 2000), which is increased in PD (DeLong, 1990). Thus, due to the ability of glial cells in maintaining the low concentration of extracellular glutamate, they prevent the risk of excitotoxic injury on neurons in the substantia nigra.

Aside from contributing to the protection of neurons against ROS and glutamate, glial and T-cells can produce trophic factors that are essential for the survival of dopaminergic neurons. Among these is the glial-derived neurotrophic factor (GDNF), which seems to be the most potent factor supporting nigrostriatal dopaminergic neurons during their period of natural, developmental death in post-natal ventral midbrain cultures (Burke et al., 1998). GDNF can be released by reactive astrocytes (Schaar et al., 1993) by the activation of microglia following a mechanical lesion of the striatum (Batchelor et al., 2000). After MPTP administration in mice, however, it seems that reactive astrocytes in the substantia nigra do not engage in a significant production of GDNF (Benner et al., 2004). Brain-derived neurotrophic factor (BDNF) is another trophic factor that can also be released by reactive astrocytes (Rubio, 1997; Stadelmann et al., 2002), by activated microglia (Batchelor et al., 1999; Stadelmann et al., 2002), and can support

the survival and development of dopaminergic structures in the striatum (Batchelor et al., 1999). Oligodendrocytes whose main function is to provide support to axons and to produce the myelin sheath which insulates axons are also a type of glial cell capable of generating trophic factors (Du and Dreyfus, 2002). For example, striatal oligodendrocytes have been shown to stimulate the survival and expression of phenotypic markers of mesencephalic dopaminergic neurons in culture (Sortwell et al., 2000). Taken together these data support the contention that glial cells, especially astrocytes, could exert neuroprotective effects in PD. Whether any of these, however, do slow the natural course of the disease in parkinsonian patients remains to be demonstrated.

26.8. Detrimental Role of Inflammation in Parkinson's Disease

In addition to the body of literature on the beneficial role of inflammation, there are also a growing number of observations supporting the concept that activation of the innate immune system could worsen neurodegeneration. Three theories have been proposed to explain the detrimental role of glial cells in diseases such as PD. The first theory is called *glial cell senescence* (Streit, 2004) which postulates that glial cells become progressively disabled during normal aging or disease progression. It is assumed with this theory that glial cells lose their functional capacity to exert the type of beneficial effects described above. In this model glial cells do not actively injure neurons, they simply stop supporting them. Although still highly speculative, some investigations would suggest that glial cells may become dysfunctional in PD. For instance, Hishikawa and collaborators (2001) have found argyrophilic, alpha-synuclein-positive inclusions in glial cells from post-mortem PD, but not from age-matched control brains. The second theory about the detrimental role of inflammation in PD is called *facilitative neurotoxicity* (Streit, 2002). During this theoretical process, glial cells will eliminate neurons that are compromised beyond viability and functionality by the primary pathological event. Based on this second model, glial cells would assume an active role in the demise of neurons that are destined to die and whose continued presence could hinder neuronal recovery. Finally, the third theory and probably the most popular in regards to the detrimental role of inflammation in PD is called *indiscriminate neurotoxicity*. Based on this third model, glial cells, upon activation, would engage in an array of cytotoxic events, which would stimulate neurodegeneration and promote both the progression and propagation of a disease such as PD. Many studies of experimental models of PD have provided over the past decade strong support for this last concept which is based on the fact that activated glial cells, especially microglia are known to produce a variety of noxious compounds including ROS, reactive nitrogen species (RNS), pro-inflammatory prostaglandins, and cytokines.

Among the range of reactive species produced by glial cells, significant attention has been given to RNS due to the

idea that nitric oxide (NO)-mediated nitrating stress could play an important role in the pathogenesis of PD (Przedborski et al., 1996, 2001; Ara et al., 1998; Pennathur et al., 1999; Giasson et al., 2000). Along this line it must be mentioned that the inducible NO synthase (iNOS) is expressed in the substantia nigra pars compacta of both PD patients (Hunot et al., 1996) and MPTP-intoxicated mice (Liberatore et al., 1999; Dehmer et al., 2000) in astrocytes and microglial cells, respectively. Myeloperoxidase and NADPH-oxidase, two pro-inflammatory enzymes which produce strong oxidants, have also been identified in PD and MPTP brain tissues (Choi et al., 2005; Wu et al., 2003). Ablation of these three enzymes have been shown to attenuate MPTP-induced neurodegeneration in mice to varying degrees (Liberatore et al., 1999; Dehmer et al., 2000; Choi et al., 2005; Wu et al., 2003), supporting the involvement of inflammation-mediated oxidative/nitrative stress in the dopaminergic neurodegenerative process.

Prostaglandins and their synthesizing enzymes, such as Cox-2, constitute another group of potential offenders. Over the past few years, Cox-2 has emerged as a key cytotoxic factor associated with inflammation (O'Banion, 1999). As mentioned above, compared to the normal basal ganglia where Cox-2 is minimally expressed, diseased basal ganglia in PD and the MPTP mouse model, Cox-2 is robustly expressed (Teismann et al., 2003). Not surprisingly, the levels of Cox-2 products such as prostaglandin E_2 were also found to be increased in the substantia nigra of PD patients (Teismann et al., 2003; Mattamall et al., 1995). In the MPTP mouse model of PD, Cox-2 induction was shown to be mediated by a c-Jun *N*-terminal kinase (JNK)-dependent mechanism (Teismann et al., 2003; Hunot et al., 2004). Noteworthy, the inhibition of JNK activation, like inhibition of Cox-2, did attenuate MPTP-induced neurodegeneration (Hunot et al., 2004; Teismann et al., 2003). Conversely, while both inhibition and ablation of Cox-2 did attenuate MPTP-induced dopaminergic neurotoxicity, deletion of the constitutively expressed isoenzyme Cox-1 had no effect (Teismann et al., 2003).

Additional glial-derived molecules with cytotoxic potentials include the large group of pro-inflammatory cytokines. The expression level of many of these toxic cytokines assessed by gene profiling appears increased in PD tissues (Mandel et al., 2005). In keeping with this result, the tumor necrosis factor- α (TNF- α) and interleukine-1 β (IL-1 β) whose levels are increased in both the substantia nigra pars compacta tissues and cerebrospinal fluids of PD patients (Mogi et al., 1994, 1996, 2000). Of note, at this point one cannot exclude that some of these alterations are related to the chronic use of the anti-PD therapy levodopa (Bessler et al., 1999). Nevertheless, in autopsy tissue from PD patients, robust immunostaining for TNF- α , IL-1 β , and interferon- γ (IFN- γ) is observed in astrocytes at the level of the substantia nigra pars compacta (Hunot et al., 1999). In terms of mechanism, these cytokines may operate in PD on at least two levels. First, once produced by reactive astrocytes, they can stimulate neighboring, quiescent astrocytes and microglia.

Consistent with this view is the upregulation of the microglial receptor Fc γ R11/CD23 in response to astrocyte-derived TNF- α , IL-1 β , and IFN- γ (Hunot et al., 1999). In this study, the authors also show that, once upregulated, ligation of Fc γ R11/CD23 stimulates the expression of iNOS and the ensuing production of NO by microglial cells (Hunot et al., 1999). Second, astrocytic and microglial-derived cytokines may also operate directly on dopaminergic neurons by binding to specific cell surface cytokine receptors such as TNF- α receptor and FAS. However, the targeting of either TNF- α receptor (Rousselet et al., 2002; Ferger et al., 2004) or FAS (Hayley et al., 2004; Landau et al., 2005) has thus far generated conflicting results in the MPTP mouse model. Findings from several studies show that ablation of these receptors decreased MPTP-induced dopaminergic neurotoxicity (Ferger et al., 2004; Hayley et al., 2004) whereas other studies found that it increased MPTP-induced dopaminergic neurotoxicity (Rousselet et al., 2002; Landau et al., 2005). Upon activation, cytokine receptors trigger intracellular death-related signaling pathways, whose molecular correlates include translocation of the transcription nuclear factor- κ -B (NF- κ -B) from the cytoplasm to the nucleus. Relevant to this is the fact that PD patients show 70 times more dopaminergic neurons with nuclear NF- κ -B immunoreactivity compared to control subjects (Hunot et al., 1997). Despite the robust recruitment of NF- κ -B, it is not clear whether this transcriptional factor is instrumental in PD pathogenesis, as mice deficient in one of NF- κ -B main polypeptide, P50, had their nigrostriatal pathway as severely damaged by MPTP as that of their wild-type counterparts (Hunot et al., 2004). As exemplified above, at this point experimental models of PD have not provided much insight into the role of cytokines in neurodegeneration of such condition as PD and related conditions.

Summary

PD is a common neurodegenerative disorder characterized by motor abnormalities and a loss of primarily but not exclusively dopaminergic neurons. Other neuropathological hallmarks of PD include the proteinaceous inclusion, Lewy body and various inflammatory changes. The inflammation is made up of resident innate and to lesser extent adaptive immune cells. Similar inflammatory changes are found in both sporadic and familial non-PD parkinsonian syndromes and in experimental models

of PD. There are some studies that suggest that inflammation initiates PD, but most investigations rather suggest that inflammation in PD is secondary to the demise of neurons. Mounting evidence indicates that inflammation in PD and related conditions can modulate the neurodegenerative process. However, there is still a lack of consensus about whether inflammation in PD plays a beneficial or a detrimental role.

Review Questions/Problems

1. What are the clinical and neuropathological hallmarks of PD?
2. What is the difference between parkinsonian syndrome and Parkinson's disease?
3. Provide examples of experimental models of PD.
4. What is the topography and composition of the inflammatory response in PD?
5. What are the similarities and differences in the inflammatory response among PD, the various parkinsonian syndromes, and the common experimental models of PD?
6. What are the arguments in favor of inflammation being a primary or a secondary event in PD?
7. How can dying dopaminergic neurons trigger inflammation in PD?
8. By which mechanisms could inflammation be beneficial in PD?
9. Name the three theories about the detrimental role of inflammation in PD and explain their respective basis.
10. Summarize the different cellular and molecular factors of inflammation that can actively mediate the demise of dopaminergic neurons in PD?
11. Which statement is incorrect about PD?
 - a. Parkinson's disease is the second most frequent neurodegenerative disorder.
 - b. The neurodegenerative process in Parkinson's disease is restricted to the dopaminergic system.
 - c. Parkinson's disease is mainly a sporadic condition.
 - d. More than 30 other neurodegenerative diseases can clinically look like Parkinson's disease.
 - e. Aside from the loss of neurons the neuropathology of Parkinson's disease includes Lewy bodies and gliosis.
12. What are the main inflammatory cells encountered in the substantia nigra of Parkinson's disease?
 - a. Astrocytes
 - b. Microglia
 - c. Oligodendrocytes
 - d. T-cells
 - e. a and b
13. Which statement is correct concerning inflammation in parkinsonian syndromes?
 - a. It is often noted, but more widespread and less detailed than in Parkinson's disease.
 - b. The type of inflammatory response differs between the sporadic and familial parkinsonian syndromes.
 - c. The syndrome multisystem atrophy is unique in that inflammation is primarily made up of infiltrating T-cells.
 - d. The neuropathological pleomorphism in patients carrying a LRRK2 mutation refers to the fact that neither Lewy bodies nor gliosis is a consistent finding.
 - e. None of the above.
14. Which statement about experimental models of Parkinson's disease is true?
 - a. Both genetic and toxic models exist, but only the former are commonly used.
 - b. Inflammation has been described in all popular models of Parkinson's disease.
 - c. The MPTP monkey model suggests that an acute intoxication produces an acute neurodegenerative event that is completed in a few days.
 - d. The MPTP mouse model suggests that the toxin provokes inflammation, which, in turn, kills dopaminergic neurons.
 - e. Neuronophagia which suggests ongoing inflammation has been described in genetics, but not in toxic models of Parkinson's disease.
15. Which of the following statements is true about inflammation in Parkinson's disease?
 - a. Free neuromelanin fails to activate microglia.
 - b. Astrocytosis is as robust as microgliosis.
 - c. The propensity of the different dopaminergic structures to degenerate in Parkinson's disease correlates with the basal density of glial cells.
 - d. Both prostaglandin and alpha-synuclein count among the factors potentially responsible for triggering inflammation in Parkinson's disease.
 - e. It is proven that prenatal infection and subsequent inflammation predispose one to Parkinson's disease.
16. Which of the following statements is most correct?
 - a. Inflammation can exert both beneficial and detrimental effects.
 - b. Most experimental models favor the beneficial role of inflammation
 - c. The detrimental role of inflammation in Parkinson's disease is due to the disease-related impairment of glial functions vital to neurons.
 - d. Contrary to astrocytes, oligodendrocytes play no role in Parkinson's disease.
 - e. Three different theories have been proposed to explain how inflammation may support the survival of dopaminergic neurons.

17. Which of the following glial functions may improve neuronal survival or regeneration?

- a. Inhibit phagocytosis.
- b. Secrete chemotactic molecules to recruit polynuclear cells.
- c. Produce trophic factors.
- d. Assist in the synthesis of neuronal superoxide dismutase.
- e. Stimulate the formation of myelin to guide new axons.

18. Glial cells can exacerbate neurodegeneration in Parkinson's disease by?

- a. Losing their ability to assist neighboring neurons.
- b. Accelerating the demise of compromised neurons.
- c. A process of indiscriminate toxicity.
- d. Decreasing extracellular glutamate levels.
- e. a, b and c

19. Regarding the cytotoxicity of inflammation, which statement is not correct?

- a. Both oxygen and nitrogen reactive species can participate in the deleterious effects of inflammation.
- b. Inactivation of NADPH-oxidase, but not of nitric oxide synthase mitigates MPTP-induced neurodegeneration in mice.
- c. The detrimental effects of inflammation on dopaminergic neurons can be mediated by soluble factors.
- d. Astrocytes and microglial cells can mutually modulate their degree of activation.
- e. Dopaminergic neurons express receptors for various deleterious cytokines.

20. Among the following inflammatory factors, which ones have been identified in the substantia nigra of patients with Parkinson's disease?

- a. Tumor necrosis factor
- b. Inducible nitric oxide synthase
- c. Interferon-gamma
- d. Myeloperoxidase
- e. All of the above

Amyotrophic Lateral Sclerosis

Ericka P. Simpson, Albert A. Yen, and Stanley H. Appel

Keywords Adaptive immune system; ALS; Chemokines; Cytokines; Innate Immune System; Microglia; Neuroinflammation

27.1. Introduction—Clinical Features

Amyotrophic Lateral Sclerosis is a devastating, relentlessly progressive neurodegenerative disease compromising lower and upper motor neurons, and resulting in death, usually from marked weakness of respiratory musculature (Haverkamp et al., 1995). The incidence of ALS is 1–2/100,000 and the prevalence is 4–6/100,000. Ninety percent of ALS cases are sporadic (sALS), while 10% are familial (fALS). The etiology of sALS is unknown, and no known pharmacotherapy has been demonstrated to significantly influence either disease progression or survival. A defect in the gene encoding copper-zinc superoxide dismutase (SOD1) is present in 20% of fALS cases (Rosen et al., 1993). In sALS, the mean age of onset is 57 years and the median survival is approximately four years with younger patients surviving longer than older individuals. Males develop sporadic ALS more frequently than females (ratio 1.7:1). However, in older individuals the frequency of female involvement is increased and the ratio approaches 1:1 over the age of 65, which is similar to the ratio in fALS.

Typical onset is characterized by complaints of weakness or functional impairment, such as difficulty writing, buttoning, or holding onto objects due to involvement of the upper extremities, or frequent stumbling, tripping, and occasional falling indicative of lower extremity involvement. Symptoms are often asymmetric and usually progress from one limb to the contralateral limb, and then proceed rostrally. Clinically, ALS is often misdiagnosed as a painless radiculopathy when initial signs and symptoms are restricted to a single limb or adjacent root and before electromyography (EMG) studies are performed. Therefore, the asymmetry and relentless progression of symptoms are diagnostically important.

In patients with bulbar involvement, symptoms of hoarseness, slurred speech, and drooling most often precede evidence

of pharyngeal muscle involvement. These bulbar symptoms, in association with tongue atrophy and fibrillations, may be the presenting feature in 20–25% of patients, for whom the majority are women over the age of 60 (Haverkamp et al., 1995). In general, onset of bulbar signs and symptoms during the disease course carries a poorer prognosis. Cognitive dysfunction due to fronto-temporal lobe involvement is a frequently associated feature in ALS patients and ranges from mild, frontal dysexecutive impairment in the majority to outright fronto-temporal dementia (Ringholz et al., 2005).

The history and physical examination provide the foundation for the diagnosis and should demonstrate the combination of lower motor neuron (LMN) involvement, manifested by weakness and muscle atrophy, and upper motor neuron (UMN) involvement, evidenced by increased tone and hyperreflexia, in at least three areas, including the limbs, tongue, and back muscles. Needle EMG and nerve conduction studies should be performed to confirm the diagnosis in all patients with suspected ALS.

27.1.1. Pathogenesis

Most studies of the pathogenesis of ALS have focused on changes within motor neurons that could reflect the mechanisms of cell injury and cell destruction. Earliest studies suggested a role for glutamate excitotoxicity (Rothstein et al., 1990, 1992; Lin et al., 1998). Other studies emphasized the importance of increased intracellular calcium (Engelhardt et al., 1997; Siklos et al., 1996, 1998) and free-radical mechanisms in mediating cell death in ALS (Bowling et al., 1993; Yim et al., 1996; Simpson et al., 2004). However, none of these explanations are mutually exclusive because altered calcium homeostasis, free radical stress, and glutamate excitotoxicity may all participate in a cell injury cascade leading to motor neuron death. In fact, alterations in one parameter can lead to alterations in other parameters, and each can enhance and propagate the injury cascade. Increased intracellular calcium can enhance free radical production (Dykens, 1994) and glutamate release, (Coyle and Putterfarcken, 1993; Tymianski et al., 1993; Dugan et al.,

1995; Carriedo et al., 1998) which in turn can further increase intracellular calcium (Sheen et al., 1992). Increased free radicals can impair the glial uptake of glutamate, increasing the extracellular glutamate available to interact with neuronal AMPA/kainate receptors, which in turn can increase intracellular calcium and/or free radicals. Free radicals can enhance lipid peroxidation leading to increased intracellular calcium (Kakkar et al., 1992). These changes of increased intracellular calcium, increased production of free radicals, and enhanced glutamate excitotoxicity could critically impair motor neuron structures such as mitochondria or neurofilaments, and compromise energy production and axoplasmic flow. Once initiated, the changes could become self-propagating and induce an irreversible cascade resulting in cell death.

Unfortunately, efforts to halt the progression of disease with therapies targeted to these proposed mechanisms of disease have shown extremely modest benefits, at best. It is not that these mechanisms are not involved, but perhaps each individual mechanism may reflect only a limited aspect of the complex pathobiology of disease. Furthermore, most studies focus solely on the neuron and fail to consider the relevance of neuronal-glial interactions. What may be missing is that neuronal injury and cell death do not occur in isolation, but may require the participation of non-neuronal cells such as microglia and astrocytes, as well as other immune cells.

27.1.2. Neuroinflammation

Neuroinflammation is a significant aspect of the neuropathology of ALS, although it is not clear whether the inflammatory cells are the cause or the consequence of motor neuron injury. Inflammatory cells and mediators are present in the vicinity of degenerating motor neurons, and recent studies have suggested that these constituents may, in fact, contribute to motor neuron injury in ALS.

The CNS was long considered to be an immune privileged site. This viewpoint has shifted over the years, as experimental evidence has clearly shown that the CNS is under constant immune surveillance and that the CNS and the peripheral immune system interact extensively. However, inflammatory processes in the CNS differ from those of systemic inflammation. Unlike the rapid, cellular infiltration seen in systemic inflammation, inflammatory responses to a noxious stimulus in the CNS can be less dramatic and may include the activation of the innate immune system, the resident microglial cells, and the presence of the adaptive immune system, lymphocytes and immunoglobulins. There is gradual entry of immune cells including dendritic cells from the peripheral circulation, as well the localized proliferation of dendritic cells within the CNS. The involvement of both innate and adaptive immune systems results in the release of cytotoxic as well as neuroprotective constituents. The initial response to an acute insult (trauma, ischemia, infection) is directed at limiting cellular damage and enhancing repair. However, under chronic insults or a continuing stimulus, a long-lasting inflammatory response

may cause additional injury to CNS tissue. In other words, the cells and signaling molecules of neuroinflammation may comprise a “double-edged sword”—sometimes protective and reparative to neurons, and sometimes injurious. Indeed, increasing evidence supports a dual role of immune activation in several CNS diseases, based upon the timing and duration of immune activation, degree and type of injury, intercellular communication, and genetic modifiers (Consilvio et al., 2004; Minagar et al., 2002).

The interrelationships between neurology and immunology have been studied extensively in multiple sclerosis, the prototypical CNS autoimmune disease. More recently, the role of neuroinflammation has been implicated in other neurodegenerative conditions, including Alzheimer’s disease and Parkinson disease (Mhatre et al., 2004; McGeer et al., 1991; McGeer and McGeer, 2002a, b, 2003; Hunot and Hirsch 2003).

27.2. Cellular and Biochemical Evidence of Neuroinflammation

27.2.1. Human ALS Studies

Although early studies of ALS tissue did not describe the presence of inflammatory cells in ALS, reports beginning in 1988 suggested that inflammatory cell infiltration might be relatively common (Troost et al., 1988, 1989; Lampson et al., 1988). Further studies (Lampson et al., 1990) demonstrated activated microglia and small numbers of T cells in degenerating white matter of ALS cords. Activated microglia are also prominent in the ventral horn of spinal cords from ALS patients. In contrast to resting microglia, which have long, highly branched processes, activated microglia have hypertrophied soma and thickened, retracted processes, first described by Rio-Hortega (1920). Reactive microglia express surface markers indicative of their activated state. These include the complement component 3 receptor 3 subunit/integrin- α M (CD11b/ITGAM); leukocyte common antigen (LCA); and major histocompatibility complex (MHC) class II glycoproteins, such as human leukocyte antigen DR (HLA-DR). In addition to serving a phagocytic function, activated microglia may also communicate with and affect the function of cells in the local environment, by expressing a broad array of cytokines, chemokines, proteases, and neurotrophic factors (Gonzalez-Scarano and Baltuch 1999).

In our early studies (Engelhardt et al., 1993), we documented the presence of lymphocytes in the spinal cord in 18 of 27 consecutive ALS autopsies. Lymphocytes were predominantly CD4-positive in the vicinity of degenerating cortical spinal tracts, and CD4 and CD8 cells were found in ventral horns. Kawamata et al. (1992) demonstrated the presence of significant numbers of CD8 T cells and, to a lesser extent, CD4 T cells marginating along capillaries in the parenchyma of spinal cord and brains of 13 ALS patients. Lymphocytes and activated microglia expressing MHC Class I and Class II,

leukocyte common antigen, Fc γ RI and β -2 integrins were present in ALS tissue.

The diversity of T cells in ALS spinal cord has also been examined employing the reverse transcriptase polymerase chain reaction (PCR) with variable region sequence specific oligonucleotide primers to amplify V β T-cell receptor transcripts (Panzara et al., 1999). A greater expression of V β_2 transcripts was detected in ALS specimens, independent of the HLA genotype of the individual. As additional confirmation, cells were assayed from the cerebrospinal fluid (CSF) of 22 consecutive ALS patients for the presence of V β_2 transcripts. This specific T-lymphocyte receptor was demonstrated in 17 of 22 ALS patients' CSF, while only 4 of 19 control patients had similar expression. It is of interest that V β_2 is a T-cell receptor known to respond to superantigens. Whether superantigen stimulation of lymphocytes with V β_2 receptors is a primary factor in motor neuron injury or the consequence of motor neuron injury due to some other cause is not known, but the presence of T lymphocyte restriction does suggest the involvement of adaptive immune mechanisms.

Further evidence supporting the importance of immune mechanisms is the presence of dendritic cells in ALS tissues (Henkel et al., 2004). Dendritic cells are potent antigen-presenting cells that initiate and amplify immune responses (Reichmann et al., 2002). They can be derived from the peripheral immune system or from resting CNS microglia. Our laboratory examined mRNA expression of dendritic cell surface markers in individual sporadic ALS (sALS), familial ALS (fALS), and non-neurological disease control (NNDC) spinal cord tissues using semiquantitative and real-time reverse transcription polymerase chain reaction (RT-PCR) (Henkel et al., 2004). Immature (DEC205, CD1a) and activated/mature (CD83, CD40) dendritic cell transcripts were significantly elevated in ALS tissues. The presence of immature and activated/mature dendritic cells (CD1a(+) and CD83(+)) was confirmed immuno-

histochemically in ALS ventral horn and corticospinal tracts. Monocyte/macrophage/microglia transcripts (CD14, CD18, SR-A, CD68) were increased in ALS spinal cord, and activated CD68(+) cells were demonstrated in close proximity to motor neurons. Increased mRNA expressions of the chemokine monocyte chemoattractant protein-1, MCP-1, which attracts monocytes and myeloid dendritic cells, and of the cytokine macrophage-colony stimulating factor (M-CSF), which stimulates the differentiation of dendritic cells and macrophages, were found in ALS tissues. The MCP-1 protein was expressed in glia in ALS but not in control tissues and was increased in the CSF of ALS patients. Furthermore, those patients who clinically progressed most rapidly expressed significantly more dendritic transcripts than patients who progressed more slowly. These results support the involvement of an adaptive immune/inflammatory response in amplifying motor neuron degeneration in ALS.

Also prevalent in ALS are reactive astrocytes, which stain intensively for the intermediate filament, glial fibrillary acidic protein (GFAP). These reactive astrocytes, with a hypertrophied appearance, are present throughout areas of degeneration. Reactive astrocytes can have multiple roles including a neuroprotective function (Liberto et al., 2004).

Numerous biochemical markers of neuroinflammation have also been found in ALS tissue. The families of compounds include cytokines, chemokines, complement proteins, prostaglandins, interleukins, interferons, integrins, acute phase reactants, apolipoproteins, and (Table 27.1). Many of these biochemical markers have also been found in Alzheimer's disease tissues, suggesting that the inflammatory response in the two conditions may be similar (Eikelenboom and van Gool 2004).

Some of the inflammatory mediators enhance the entry of leukocytes from the periphery into the areas of degeneration. As noted above, MCP-1 is well known to enhance the entry of

TABLE 27.1. Proteins associated with the inflammatory state observed in ALS tissues.

LCA (leukocyte common antigen, CD45)	Membrane-bound protein tyrosine phosphatase; expressed by all hematopoietic cells
LFA-1 (leukocyte function antigen 1, CD11a/CD18 integrin)	Appears on all leukocytes; promotes intercellular adhesion
ICAM-1 (intracellular adhesion molecule 1, CD54)	Cell surface or matrix molecule; promotes binding to LFA-1
GFAP (glial fibrillary acidic protein)	Intermediate filament protein highly expressed by activated astrocytes
Phospholipase A2	Breaks down membrane lipids to form arachidonic acid
COX-1 (cyclooxygenase-1)	Converts arachidonic acid into prostaglandin H ₂ ; rate-limiting step in prostaglandin synthesis
COX-2 (cyclooxygenase-2)	Converts arachidonic acid into prostaglandin H ₂ ; rate-limiting step in prostaglandin synthesis;
inducible expression	
PGE2 (prostaglandin E2)	Member of prostaglandin family; may have both pro- and anti-apoptotic actions
Fc γ R-1 (immunoglobulin Fc region receptor 1)	Receptor on phagocytes for IgG bound to an antigen
HLA-DR (human leukocyte antigen DR)	Antigen-presenting surface molecule on immunocompetent cells
IL-6 (interleukin 6)	Inflammatory cytokine released by activated astrocytes and microglia
MCP-1 (monocyte chemoattractant protein-1)	Chemokine that attracts monocytes and myeloid dendritic cells
M-CSF (macrophage-colony stimulating factor)	Growth factor cytokine that acts on monocytes and macrophages to cause them to differentiate
MMP-9 (matrix metalloproteinase-9)	Proteolytic enzyme that can degrade components of the extracellular matrix
C3d (complement C3 fragment d)	Degradation product of activated C3
C4d (complement C4 fragment d)	Degradation product of activated C4
CD-11b (complement receptor 3)	Phagocyte surface receptor recognizing an activated complement fragment from C3
g-Interferon	Inflammatory cytokine released by activated T cells; potent activator of microglia and leukocytes

monocytes and dendritic cells into tissues based on interaction with the cognate receptor CCR2 on invading cells. Leukocytes that are observed in the postcapillary venules also express leukocyte function-associated antigen 1 (LFA-1), a surface molecule, which gives activated leukocytes the ability to adhere to endothelial cells and migrate into CNS tissue. This binding involves a specific interaction between LFA-1 and intercellular adhesion molecule-1 (ICAM-1), an adhesion molecule that is up regulated on endothelial cells in areas of inflammation (McGeer and McGeer, 2003). Another molecule that is up regulated in ALS tissue is matrix metalloproteinase-9 (MMP-9) (Lim et al., 1996). MMP-9 is a proteolytic enzyme that is released by leukocytes and reactive astrocytes to degrade proteins of the extracellular matrix and enhance the entry of leukocytes into areas of inflammation.

Prostaglandins represent inflammatory molecules with both pro-apoptotic and anti-apoptotic actions (Bezzi et al., 1998; Kawamura et al., 1999). In the first step of prostaglandin production, membrane lipids are broken down by phospholipase A₂ to arachidonic acid. Interestingly, phospholipase A₂ has been identified in activated glial cells in areas of neurodegeneration (Stephenson et al., 1999). Next, cyclooxygenase (COX) catalyzes the rate-limiting step of prostaglandin synthesis: the conversion of arachidonic acid to prostaglandin G₂ (PGG₂). Two distinct COX isoenzymes, COX-1 and COX-2, can mediate this reaction, and they are 65% homologous. COX-1 is constitutively expressed in most tissues, and COX-2 is constitutively expressed in the kidney, stomach, and CNS. However, COX-2 expression is strongly inducible and can be significantly up regulated by several cellular factors, including multiple growth factors, interleukin-1 β , tumor necrosis factor- α , lipopolysaccharide (LPS), phorbol ester, and elevated intracellular calcium concentration. A marked increase in COX-2 levels has been seen in ALS spinal cords, consistent with previous reports of increased levels of prostaglandin E₂ (PGE₂), a further product of prostaglandin synthesis (Almer et al., 2002). Both mRNA and protein levels of COX-2 were elevated in ALS spinal cords, and only in pathologically affected areas (Almer et al., 2001; Yasojima et al., 2001).

Additionally, immunoglobulin G (IgG) is present in motor neurons in ALS spinal cords, and also in pyramidal cells of the motor cortex (Engelhardt and Appel, 1990).

27.2.2. Animal Models

Transgenic mice (Gurney et al., 1994; Wong et al., 1995) and rats (Howland et al., 2002) over expressing mutant Cu²⁺/Zn²⁺ superoxide dismutase 1 (mSOD1) develop a progressive motoneuron disease that resembles the clinical and pathological features of human familial amyotrophic lateral sclerosis (ALS). However, the mechanisms by which mSOD1 causes selective motoneuron death are not clearly defined. Increasing evidence suggests that motoneuron degeneration in ALS is non-cell autonomous, i.e., non-neuronal cells contribute to the

pathogenesis of ALS. Although intracellular accumulation of mSOD1 damages motoneurons *in vitro* (Durham et al., 1997) expression of mSOD1 either in astrocytes (Gong et al., 2000) or in neurons (Pramatarova et al., 2001; Lino et al., 2002) does not induce an ALS-like disease in mice. Elegant data from chimeric mice, using the original mSOD1 promoter, in the same genomic location, and with the same number of copies, suggest that mSOD1-overexpressing neurons surrounded by normal glia remained relatively intact, whereas normal neurons surrounded by mSOD1-overexpressing glia showed signs of injury (Clement et al., 2003).

This observation of non-cell autonomy raises the potential importance of non-neuronal cells such as innate immune microglia and adaptive immune lymphocytes in the pathogenesis of motoneuron injury in ALS.

At 40 days of age, a presymptomatic stage, spinal cord from mSOD1 transgenic mice has increased ICAM-1 expression, deposition of immunoglobulin G (IgG) within motor neuron cell bodies, and increased Fc receptor (FcR) expression on microglia (Alexianu et al., 2001). Activated microglia are present as early as 80 days of age, prior to evidence of motor weakness (Hall et al., 1998). In general, the development of these inflammatory changes precedes the onset of motor signs, and their increasing levels parallel disease progression. Multiple studies have confirmed an elevation of pro-inflammatory molecules in the presymptomatic mSOD1 mouse, including such mediators as TNF- α , COX-2, inducible nitric oxide synthase (iNOS), interleukin-1 β , IL-1 receptor antagonist (IL1RA), CD86, CD200R, and growth-related oncogene- α , (Gro- α) (Almer et al., 1999; Hensley et al., 2002; Yoshihara et al., 2002).

Evidence for neuroinflammation has also been found in other animal models of motor neuron degeneration. For example, microglial activation was observed in the Wobbler mouse, a finding that has been confirmed by several groups (Rathke-Hartlieb et al., 1999; Boillee et al., 2001). Elevated TNF- α levels were found in the brain and spinal cord of the *mnd* mouse (Ghezzi et al., 1998). It appears that these other murine models of motor neuron degeneration share some neuroinflammatory features with the mSOD1 model.

27.2.3. In Vitro Studies

To help define the interactions involving non-neuronal cells, such as microglia and astrocytes, we used primary MN cultures to investigate the effects of microglia activated by lipopolysaccharide or IgG immune complexes from patients with amyotrophic lateral sclerosis (Zhao et al., 2004). Following activation, microglia induced MN injury, which was preventable by a microglial inducible nitric oxide synthetase (iNOS) inhibitor as well as by catalase or glutathione. Glutamate was also required to elicit MN injury, as evidenced by the finding that inhibition of the motoneuron AMPA/kainate receptor by CNQX prevented the toxic effects of activated microglia. In fact, peroxynitrite, a toxic product of nitric oxide metabolism, and glutamate were

synergistic in producing MN injury. The addition of astrocytes to cocultures of MN and activated microglia prevented MN injury by removing glutamate from the media. Such data suggest that free radicals released from activated microglia may initiate MN injury by increasing the susceptibility of the MN AMPA/kainate receptor to the toxic effects of glutamate. A recently published novel experiment suggests that mSOD1 released from motor neurons derived from transgenic mice could activate microglia, and, in turn, lead to motor neuron injury and cell death (Urushitani et al., 2006).

27.2.4. Conclusions

The cellular evidence for neuroinflammation in ALS consists of activated microglia, reactive astrocytes, macrophages, and a few T cells seen marginating along postcapillary venules. The biochemical evidence consists of the presence of cytokines, chemokines, components of prostaglandin synthesis, and other pro-inflammatory molecules. In vitro data clearly document that immune/inflammatory constituents can mediate cytotoxicity. In vivo data from animal models also provide evidence that glial cells, such as microglia, and infiltrating immune cells can mediate cytotoxicity. The role that these immune responses could play in mediating neuroprotection in ALS is presently being studied in animal model studies. However, it remains for translational research studies of human ALS to document that both neuroprotective and cytotoxic mechanisms are involved in the pathogenesis of ALS, and to harness such processes for therapeutic benefit.

27.3. The Failure of Immunosuppression in ALS

Immunosuppression with steroids, cyclophosphamide, plasmapheresis, and even total lymphoid irradiation have been reported to be ineffective in halting the progression of ALS (Brown et al., 1986; Drachman et al., 1994). Our own study with cyclosporine suggested a possible slowing of the course of ALS in a subpopulation of patients with no effect on the overall population (Appel et al., 1988). The major problem in that study was the toxic side effects of the immunosuppression, and the necessity for lowering medication doses to levels, which failed to suppress the inflammatory responses in the CNS.

The fact that immunosuppressant therapy has not been proven to halt progression has been cited as evidence against an immune-mediated mechanism of motor neuron injury. However, several potential explanations for this lack of efficacy could exist. Immune suppression may be too little and too late. By the time symptoms and signs appear, extensive CNS damage may already have occurred due to increased calcium and free radicals, and it may be difficult to stop the process that the immune reactivity initiated. Further, immunosuppression therapies may not adequately access the CNS and

suppress the selective inflammatory reactions there, especially microglial responses and/or dendritic cells. Immunosuppression has similarly failed to ameliorate type-1 diabetes or other immune mediated endocrinopathies without invalidating the important role of immune mechanisms in initiating those disorders. In addition, in chronic progressive multiple sclerosis, characterized by marked CNS immune/inflammatory lesions, immunosuppression is of limited value. Further, what initiates the disease may be different from what propagates the disease (increased calcium, free radicals and glutamate) or administers the final cellular *coup de grace* (e.g. dendritic cells, T cells and/or activated microglia). Finally, if both cytotoxic and neuroprotective mechanisms are being mediated by the immune system, then suppression of such immunity may suppress protective as well as toxic mechanisms.

Clearly, the death of neurons may no longer require the initial immune-mediated cell injury, but may result from alterations in intracellular calcium and free radicals through a number of processes, any of which may initiate an apoptotic cascade. Thus, the failure of immunosuppression does not, per se, invalidate the possible participation of immune/inflammatory mechanisms in the pathogenesis of motor neuron injury and death in ALS. Similarly, the lack of meaningful efficacy of drugs that target glutamate excitotoxicity (e.g. riluzole) does not negate the role of glutamate in the pathogenesis of motor neuron injury in ALS.

27.4. Evidence for a Role in Initiating Disease

The pathology of ALS suggests the activation of both innate and adaptive arms of the immune system, involving antigen capture and presentation, leukocyte migration and trafficking, and microglial activation. Whether these processes are sufficient to initiate motor neuron injury in ALS is unknown, but early studies that searched for an initiating role of an immune response against "self" epitopes (autoimmunity) raised some intriguing possibilities (Appel et al., 1993). For example, an animal model of a primary, immune-mediated motor neuron disease was developed by inoculating guinea pigs with bovine motor neurons. Clinical features of this experimental autoimmune motor neuron disease animal included muscle weakness, electrophysiologic and morphologic evidence of denervation, loss of motoneurons in the spinal cord, and clinical improvement with immunosuppression (Engelhardt et al., 1989; Engelhardt et al., 1990; Garcia et al., 1990; Tajti et al., 1991). These studies documented that a primary immune process is capable of initiating motor neuron disease, but it was still unknown whether autoimmunity was playing a role in ALS. Although the higher incidence of autoimmune diseases and paraproteinemias in ALS patients continues to suggest a link between dysimmunity or paraimmunity and motor neuron disease (Haverkamp et al., 1995; Gordon et al., 1997), the

evidence that ALS is a primary, autoimmune disease remains circumstantial.

The possibility that ALS pathogenesis is initiated by a secondary immune response to a primary infectious agent has also been considered, especially in regards to viral exposure. Studies attempting to detect viruses in ALS tissue have been unconvincing even with the application of sensitive detection techniques (Walker et al., 2001; Nix et al., 2004). Following the onset of the HIV/AIDS epidemic, renewed interest arose with reports of several cases of HIV-associated motor neuron disease (Hoffman et al., 1985; Simpson and Tagliati 1994; MacGowan et al., 2001; Moulignier et al., 2001). Compared to classic ALS, HIV-associated ALS occurs in younger patients, progresses more rapidly, and improves with antiretroviral therapy—this response suggests that HIV virus is the etiologic factor in motor neuron dysfunction in these cases. Further studies indicated that the HIV retrovirus infects and replicates within macrophage/microglia cell populations and seems to exert its neurotoxic effects indirectly via Tat, a transcriptional regulator viral protein. The Tat protein affects the functional state of infected microglial cells by stimulating them to secrete neurotoxic molecules, differentially regulating chemokine expression within the brain, and disrupting pathways regulating intracellular calcium and ion channel expression (D'Aversa and Berman 2004). Both *in vitro* models and pathological studies suggest that the HIV-infected/activated microglia and macrophages may selectively damage susceptible neurons, leading to neuropathology (Yi et al., 2004).

Additional support for an association between retroviruses, immune activation, and ALS is provided by a murine neurotropic retrovirus, which can cause motor neuron degeneration in mice (Gardner et al., 1973), and the human T-cell lymphotropic virus type I (HTLV-1) retrovirus, which predominantly causes myelopathy/tropical spastic paraparesis but has caused an ALS-like syndrome in rare cases (Matsuzaki et al., 2000). Based on this information, it has been proposed that an immune response directed against retroviral proteins induces a chronic neuroinflammatory state that leads to motor neuron degeneration. In accord with this, antibodies against HTLV-1 viral proteins have been reported in some ALS patients, as well as increased reverse transcriptase activity in ALS sera (Ferrante et al., 1995; Andrews et al., 2000). Furthermore, this process may not even require infection and active replication by an exogenous retrovirus. A recent study showed that an immune response can be directed against retroviral proteins produced by activation of endogenous retrovirus sequences that are normally present in the human genome. In that study, the researchers reported that 56% of sporadic ALS patients had IgG antibodies reactive to a protein encoded by the endogenous retroviral sequence, HML-2/Herv-K, and that this immune response was identified in ALS patients more than five times as frequently as in Alzheimer's disease or healthy controls (Hadlock et al., 2004). Together, these findings raise the possibility that the activation of endogenous retroviruses

can perpetuate and drive ongoing inflammatory events, at least in a subset of ALS patients.

27.5. Evidence for a Role in Amplifying Disease

Although the evidence that CNS inflammatory events can initiate disease is still questionable, a growing consensus among ALS researchers is that inflammatory cells and mediators play an integral role in affecting motor neuron survival. In addition to the activated microglia, dendritic cells, immunoglobulins, and inflammatory proteins mentioned earlier, we recently documented increased levels of monocyte chemoattractant protein-1 (MCP-1 in ALS spinal cords (Henkel et al., 2004), and that the MCP-1 is expressed mainly by glial cells. MCP-1, a chemokine that attracts myeloid dendritic cells, macrophages, and activated T cells, is also elevated in the CSF and serum of ALS patients, compared to controls (Simpson et al., 2004; Wilms et al., 2003). This elevation may reflect a local inflammatory response that results in an active transmigration of cellular constituents from the periphery into the CNS. Overall, the presence of T cells, immunoglobulins, and dendritic cells suggests that the immune inflammatory response in ALS is involved in CNS tissue injury and likely, in repair.

27.6. Evidence for a Role in Repair and Protection
